Badanoiu *et al.* (2015a) prepared alkali activated binders by activating WG powder from green glass cullet and binary mixtures of WG (90%, 75%) and RM (10% and 25%) using 5 M NaOH solution as activator. Covered mortar specimens were cured at 60°C for the 1st day, then after de-molding at 60°C in 85% R.H. and then stored at $20 \pm 2^\circ\text{C}$ in the same R.H. until the testing time. The increase in pre-curing time at 60°C (from 1 to 3 days) resulted in higher compressive strengths, especially for binary mixtures containing RM of less reactivity. The plain WG binder exhibited compressive strengths between 15 and 17 MPa after 1–3 days of pre-curing and about 25 MPa if cured to the age of 7 days at 20°C in air. The increase in pre-curing time, however, decreased the stability of the material in water. Fig. 11 displays the influence of initial curing time at 60°C on compressive strength of alkali activated binders.

In a different work, the same authors (Badanoiu *et al.*, 2015b) used brown glass cullet and RM in preparation of geopolymer foam. Glass powder and a mixture of glass powder (75 wt%) and RM (25 wt%) were used as geopolymer precursor. A 5 M NaOH solution and filtrate from RM slurry processing with a pH of 12.96 were used as two different alkali activators. Geopolymer paste specimens prepared with liquid-to-solid ratio of 0.30 were cured at 60°C for the 1 day and then at 20°C in 85% R.H. for 6 days. The cured specimens were then subjected to different high temperatures (400, 600, 700, and 800°C) for 1 h at the heating rate of $10^\circ\text{C}/\text{min}$. Apparent densities lower than $0.866 \text{ g}/\text{cm}^3$ with a minimum compressive strength of 2 MPa were achieved by thermally treating waste-glass geopolymer at temperatures in the range $600\text{--}800^\circ\text{C}$. SEM studies confirmed the formation of open pores of

Fig. 11 Compressive strength versus initial curing time at 60°C (G: alkali activated binder from WG, GR25: alkali activated binder from 75% WG and 25% RM). Reproduced from Badanoiu, A.I., Al Saadi, T.H.A., Voicu, G., 2015a. Synthesis and properties of new materials produced by alkaline activation of glass cullet and red mud International. Journal of Mineral Processing 135, 1–10.

Fig. 12 Compressive strength of RM/FA geopolymer prepared from class C-FA and RM from desulfurization process. Reproduced from Nie, Q., *et al.*, 2016. Strength properties of geopolymers derived from original and desulfurized red mud cured at ambient temperature. *Construction and Building Materials* 125, 905–911.

the sizes between 1 and 100 μm due to foaming of sodium silicate (aluminate) hydrates. The presence of refractory crystalline phases in RM resulted in a higher foaming temperature (700–800°C) for the binary mixture of WG and RM. Geopolymer from binary mixture activated with filtrate from RM slurry exhibited a contraction due to partial melting when thermally treated at 700°C.

Kaya *et al.* (2016) studied the influence of RM on compressive strength and structural characteristic of MK-based geopolymer. Incorporation of RM into MK-based geopolymer at different replacement levels (10–40 wt%) resulted in dramatic loss of compressive strength and microstructural integrity. Based on XRD and FTIR spectroscopy data, this behavior from RM was attributed to iron oxide content of RM, which tends to reprecipitate as hydroxide consuming the hydroxide anions of the alkali activator in the reacting medium.

Nie *et al.* (2016) studied the possibility of using RM in binary blend of RM (50%)/FA (50%) as geopolymer precursor. Two types of FA (class C and class F) and two types of RM (original RM from Bayer process and RM used for flue-gas desulfurization in a power plant) were used and the binary blends were activated with NaOH solutions of varying concentrations. The prepared cylindrical paste specimens were cured at 20°C. The geopolymer containing RM from desulfurization process exhibited higher 28-day compressive strength (20.3 MPa) than the geopolymer derived from original RM (15.2 MPa) at optimum NaOH concentrations of 3.5 M and 2.5 M, respectively. Class C-FA with a higher CaO content (about 20%) was found to be more suitable than class F-FA for geopolymer preparation at ambient temperature. The higher 28-day compressive strength of geopolymer containing RM from desulfurization process was attributed to its Na_2SO_4 content resulted from desulfurization, which can take part in the activation process. Fig. 12 depicts the effect of SH concentration on different age compressive strength of RM/FA geopolymer prepared from class C-FA and RM from desulfurization process.

Choo *et al.* (2016) investigated the feasibility of preparing one-part FA geopolymer using RM as a solid alkali activator. They used five different FAs of relatively high unburned carbon contents ($\text{LOI} > 7.5$). RM of about 12 wt% Na_2O content was used as activator and incorporated into FA at different replacement levels ranging from 0% to 60%. For comparison purposes, a number of one-part FA geopolymers of varying NaOH pellet contents were also prepared. The paste specimens were cured at room temperature for 1 day and then at 60°C for 3 days. The alkalinity of RM at higher replacement levels promoted the geopolymerization reactions resulting in maximum unconfined compressive strengths up to 1.5 MPa. They concluded that one-part FA geopolymer prepared with RM as a solid alkali activator can be considered as a controlled low strength product. The effect of RM content on unconfined compressive strength of one-part FA geopolymers is displayed in Fig. 13.

Ye *et al.* (2016) prepared one-part RM-based geopolymer by activating RM both chemically and thermally. NaOH pellets were firstly incorporated into RM at two different levels corresponding to 10 and 15% Na_2O by the weight of RM and the mixtures were then calcined at 800°C for 1 h. Silica fume was incorporated into the mixture at different levels ranging from 0% to 30% by the weight of total solid to improve the chemical composition ($\text{SiO}_2/\text{Al}_2\text{O}_3$ molar ratio) of the mixture and the prepared paste specimens were cured at $20 \pm 1^\circ\text{C}$ in sealed condition. The maximum 28-day compressive strength of 31.5 MPa was achieved from the mixture containing 10 wt% Na_2O and 25 wt% silica fume at the reduced water-to-solid ratio of 0.45 by adding sodium lignosulphonate (0.5 wt%) as dispersant. Based on pH measurements in leaching tests performed on one-part geopolymer binders, it is concluded that incorporation of silica fume increased the stability of geopolymerization products in water. In a later complementary work and using X-ray Photoelectron Spectroscopy (XPS) to determine the binding energies of Al-O and Si-O bonds in both the chemical-thermal activated RM and the geopolymer samples, Ye *et al.* (2017a) observed that binding energies of Al2p and Si2p in raw RM tends to decrease upon chemical-thermal activation and then to increase upon geopolymerization confirming that chemical-thermal activation of RM damages the aluminosilicate structure of raw RM and increases the reactivity of the material by decreasing the binding energies of Al-O and Si-O bonds. Based on Mössbauer spectroscopy results, they also concluded that chemical-thermal activation of RM transforms the octahedral Fe^{3+} present in raw RM mainly into tetrahedral Fe^{3+} and partially into hematite. Geopolymerization, however, transforms most of Fe^{3+} to structural octahedral Fe^{3+} again confirming that coordinated Fe^{3+} in raw RM plays a role similar to Al^{3+} and can replace it in the geopolymer molecular structure.

Fig. 13 The effect of RM content as solid alkali activator on unconfined compressive strength (UCS) of one-part FA geopolymers. Reproduced from Choo, H., *et al.*, 2016. Compressive strength of one-part alkali activated fly ash using red mud as alkali supplier. *Construction and Building Materials* 125, 21–28.

Krivenko *et al.* (2017) investigated the feasibility of preparing alkali activated cement and concretes containing high volumes of RM. They activated different combinations of RM (50–80 wt%), GGBFS (15–50 wt%) and OPC (5–10 wt%) using sodium carbonate, sodium metasilicate and liquid SS as different alkali activators. They also incorporated a high volume of RM (up to 38.6% by mass of dry constituents), as fine aggregate, into concrete mixes based on alkali activated GGBFS ($\approx 97\%$)/OPC (3%) activated with liquid SS. The properties of alkali activated cements and concretes were determined in accordance with Ukrainian national standards. Paste specimens of cement formulation comprising of 60% RM, 30% GGBFS, and 10% OPC activated with liquid SS and cured at $20 \pm 2^\circ\text{C}$ and $95 \pm 4\%$ R.H. exhibited compressive strengths up to 60 MPa after 28 days. They reported compressive strengths up to 70 MPa for concrete mixes. Based on XRD analyses results, the main hydration products were identified as CSH, clinoferrrosilite (FeSiO_3) and lawsonite ($\text{CaAl}_2[\text{Si}_2\text{O}_7](\text{OH})_2 \cdot \text{H}_2\text{O}$). Evaluating the radiological properties, they also confirmed the safety of the developed alkali activated concrete for road construction.

Ascensao *et al.* (2017) developed porous geopolymer of alkali diffusion and pH buffering capabilities over relatively long term for applications in biogas generation in anaerobic digestion and wastewater treatment. They activated blends of MK/RM using a combination of 10 M SH solution with a high amount of liquid SS as activator and aluminum powder as pore forming agent. The specimens sealed in plastic film were cured at 40°C and 65% R.H. for 7 days and then at normal conditions. Incorporation of high level of RM (> 35 wt%) in the presence of optimum amount of pore forming agent (< 0.025 wt%) resulted in the development of geopolymer of increased alkali content and enlarged open porosity exhibiting a prolonged high buffer capability.

Geng *et al.* (2017) investigated the feasibility of producing geopolymer from RM and coal gangue (CG) blends with RM contents ranging from 50 wt% to 90 wt%. They prepared two geopolymer series (I and II) by applying two different preparation procedures. Series I samples were prepared by firstly dry ball milling the blends followed by alkali activation and then curing thermally at 80°C for 24 h and normally at room temperature for 27 days. Series II samples were prepared by firstly calcining the blends at 800°C for 2 h followed by dry ball milling, then alkali activation and finally curing normally at room temperature. Mixtures of SH (5 M) and water glass were used as alkali activator. The results showed that the preparation procedure applied to series I samples was more effective and the optimum blend consisting of 80 wt% RM and 20 wt% CG exhibited maximum compressive strength of 30.25 MPa.

Croymans *et al.* (2017) evaluated the radiological properties of alkali activated concretes incorporating different amount of RM as fine aggregate. A composition of 87 wt% GGBFS, 5 wt% OPC, 4 wt% Na_2CO_3 and 4 wt% $\text{Na}_2\text{O} \cdot \text{SiO}_2 \cdot 5\text{H}_2\text{O}$ was used as alkali activated cement. Based on Markkanen activity concentration indexes, they concluded that the studied RM can be incorporated into concrete up to 90 wt% for road construction applications. For building construction applications and considering Radiation Protection (RP) 122 (0.3 mSv/a), they recommended incorporations less than 75 wt%.

Hu *et al.* (2018) investigated the possibility of utilizing RM along with different low-calcium (Class F) and high calcium (class C) FAs in preparation geopolymer. They activated RM/FA (50:50) blends either with SH solutions of varying concentrations or with mixtures of SS and SH. The cylindrical paste specimens were cured either at 20°C or at 60°C for 24 h and then at ambient temperature. Compared to RM/FA (class C) showing 28-day compressive strength up to about 15 MPa, combination of RM/FA (class F) exhibited almost no reactivity when activated with SH and cured under normal curing condition. The reactivity of RM/FA (class C) combination under normal curing condition was attributed to CaO content of class C-FA. Based on the results of this study, the low reactivity of RM/FA (class F), however, can be improved and compressive strengths up to about 30 MPa can be achieved by applying elevated temperature curing condition and using a relatively high concentration SH solution or mixtures of SS and SH as activators.

Fig. 14 7-day compressive strength of ambient cured geopolymers of different RM contents prepared from processed and unprocessed RMs. Reproduced from Singh, S., *et al.*, 2018. Effect of mechanical activation of red mud on the strength of geopolymer binder. *Construction and Building Materials* 177, 91–101.

Singh *et al.* (2018) studied the influence of RM fineness on compressive strength of RM/FA geopolymer. Binary blends of RM/FA consisting of 0%–90% by weight RM, prepared from both unprocessed and pulverized RM (GRM), were activated with combinations of SS and SH. After 2 days from casting, the paste specimens were cured either thermally at 60°C for 24 h or at ambient conditions (28–34°C and 50%–60% RH). To improve the chemical composition and the reactivity of the blends, 10 wt% microsilica was incorporated to geopolymers cured thermally and 10 wt% GGBFS to those cured at ambient. Based on results, mechanical activation of RM negatively impacts compressive strength under thermal curing conditions. They attributed this surprising observation to the reduced size and size range of nanopores in pulverized RM that in turn could result in the formation of shrinkage cracks under thermal curing conditions. Pulverization of RM, however, showed significant positive impact on compressive strength under ambient curing conditions and 7-day compressive strengths up to 40 MPa were achieved (see Fig. 14).

Chen *et al.* (2019) utilized RM/GGBFS blends in preparation of pervious concrete for adsorption of heavy metals. In this work, binary blends of RM/GGBFS with RM contents of 0, 30, and 50 wt%, limestone gravel and mixtures of SS and SH of varying concentrations were used to prepare pervious concrete. Washed RM was also used to investigate the influence of RM alkalinity on concrete strength. Concrete cubes were cured in the mold for 1 day and then in a curing chamber at $20 \pm 1^\circ\text{C}$ and 95% RH. Portland cement pervious concrete was also prepared and used for comparison purposes. The 28-day compressive strength of pervious concrete was significantly reduced with RM content. The role of alkali content of RM, however, was significant in activating the binary blend. The maximum 28-day compressive strength was 18.53 MPa from the concrete mix prepared from binary blend containing 30 wt% activated with an optimum alkali concentration of 6 wt%, which is claimed to be sufficient for light road pavement. RM, however, exhibited a strong positive impact of heavy metal adsorption capacity of geopolymer concretes and all geopolymer pervious concretes performed better than OPC pervious concrete. The binary blend containing 50 wt% RM showed maximum adsorption capacities of 84.03%, 64.16%, 63.30%, and 62.6%, for Pb^{2+} , Cd^{2+} , Cu^{2+} , and Cr^{2+} , respectively. The high adsorption capacity of geopolymer pervious concretes was attributed to both hydration products (geopolymer and CSH gels) and raw RM particles showing a high tendency for heavy metal adsorption.

Miscellaneous Aluminosilicate Industrial Wastes

Pacheco-Torgal *et al.* (2008b) studied the potential of a geopolymeric binder based on tungsten mine waste mud as a repair material for OPC-concrete. They used a mixture of thermally treated tungsten mine waste mud, hydrated lime, and coarse aggregate activated with SS and SH and exhibiting a 28-day compressive strength of about 78 MPa as repair material in slant shear test for evaluating its bond strength to OPC-concrete. Compared to reference commercial repair products, geopolymeric binder exhibited a very high bond strength even at low surface treatment roughness. In a series of studies, Pacheco-Torgal (2008a,b, 2009; Pacheco-Torgal *et al.*, 2008a) investigated the properties of similar geopolymeric mortars prepared from different aggregates. They faced difficulties in evaluating the workability of the fresh mortars due to their high stickiness to flow table. The setting time was reported to be dependent on alkali concentration, hydrated lime content and composition of alkali activator (SS/SH mass ratio). All the mortars exhibited relatively low values of unrestrained shrinkage and water absorption. A 10% hydrated lime was reported as optimum value resulting in the maximum compressive strength. All the mixes containing higher amounts of hydrated lime exhibited a strength decrease after 2 weeks of curing. Since compressive strength showed significant dependency on aggregate type and based on SEM observations, they suggested that some aggregate types (e.g., schist and granite) are chemically reactive and their partial surface dissolution in the reacting medium enhances the paste-aggregate bonding resulting in a denser and more uniform interfacial transition zone and higher compressive strengths. SEM and EDS analyses confirmed the formation of N–A–S–(H) and C–S–H gels as the hydration products. They also detected the formation of phlogopite as a new crystalline phase. Silva *et al.* (2012) studied the water-immersion behavior of alkali activated binder

prepared from calcined tungsten mine waste mud activated with a mixture of SS and SH (10 M). They reported that all specimens cured at 20°C (40% RH), especially those cured for less than 28 days, exhibited structural disintegration and loss of strength when immersed in water irrespective of the mix proportion. Specimens cured at elevated temperature 80°C (dry condition) and 130°C (dry condition), however, showed apparently higher structural stability irrespective of curing time period. Using data published on MK- and tungsten mine wastes-based geopolymer mortars (Pacheco-Torgal *et al.*, 2008a, 2011; Nazari *et al.*, 2014) developed a neuro-fuzzy interfacial systems-based model for investigating the influence of synthesis parameters on mechanical strength behavior. The study confirmed the alkali concentration as the main influencing factor, compared to curing time, hydrated lime content, alkali concentration, aluminosilicate source, H_2O/Na_2O molar ratio, and mold type. Based on the predicted results, they also reported a strength decrease after 28 days of curing.

Ahmari and Zhang (2013a) prepared geopolymer bricks from copper mine tailings and investigated the effect of cement kiln dust (CKD, 0%–10%), SH concentration (10 and 15 M) and water content (12%–20%) on brick properties and its mass and compressive strength loss after water immersion. The bricks were cured in an oven at 90°C for 7 days. Significant improvements in brick properties and durability were observed with incorporation of CKD. The improving effect of CKD was attributed to its effective contribution in geopolymerization reactions, formation of calcium carbonate, and filling effect. In a later study, the same authors (Ahmari and Zhang, 2013b) studied the durability performance and leaching behavior of geopolymer bricks in pH 4 and 7 solutions. The oven-cured (90°C) geopolymer bricks prepared by activating the mine tailings with 15 M SH solution at different moisture contents (8% to 18%) and forming pressures (0–35 MPa) exhibited substantial loss of unconfined compression strength (53% to about 78%) after 4 months of immersion. The leaching results, however, confirmed an effective immobilization of heavy metals. This strength loss was attributed to unsuitable chemical composition of mine tailings (relatively high Si/Al ratio) leading to partial geopolymerization.

Ye *et al.* (2017b) prepared geopolymer binder from binary blend of ore-dressing tailing of bauxite (70 wt%) calcined at 800°C for 1 h and slag (30 wt%) using a 20% SS solution (dry basis) as activator. They cured mortar specimens at $20 \pm 1^\circ\text{C}$ in a humid chamber (95 ± 5 R.H.) for 1-year and then in a base room with a temperature in the range 18–22°C and a R.H. between 40% and 80% and investigated their mechanical strength evolution. They reported gradual increases in both flexural and compressive strengths accompanied with gradual decrease in cumulative pore volume confirming continuous geopolymerization. The compressive strength with a 28-day value of 50.0 MPa reached to values as high as 75 after 6 years.

Kiventera *et al.* (2018) investigated the possibility of immobilizing heavy metals of gold mine tailings by alkali activation. They used paste specimens prepared from ternary blends of gold mine tailings (40–50 wt%), GGBFS (20–30 wt%) and MK (30 wt%) activated with mixtures of SH (8 and 9 M) and SS and cured in sealed plastic bags at room temperature for 24 h and then in ambient conditions (50–60 R.H.) for 7 and 28 days. The results showed high immobilization efficiencies for Cr, Cu, Ni, Zn, and Mn, which were improved with curing time. Leaching amount for As, which was high after 7 days of curing, significantly decreased with curing time. The leaching amounts for Sb, B, and V were increased with geopolymerization due to their tendency to form oxyanions with a negative oxidation state in alkaline media.

Dabbabi *et al.* (2018) investigated the possibility of converting calcined washing waste of phosphate industry into geopolymer. Phosphate washing waste (PWW) calcined at different temperatures (600, 700 and 800°C) and activated with SS and 10 M SH was used to prepare mortar specimens. They reported a maximum compressive strength of 11 MPa for geopolymer mortar prepared from PWW calcined at 700°C after 28 days of curing under laboratory ambient conditions. The geopolymer mix prepared from PWW calcined at 800°C exhibited a flash setting behavior upon mixing of ingredients.

Han *et al.* (2018) used an industrial waste called electrolytic manganese dioxide residue (EMDR) as a precursor for geopolymer preparation using phosphoric acid as activator. EMDR is mainly composed of quartz, aluminum sulfate hydrate and magnetite and therefore cannot be considered as an aluminosilicate material. They achieved compressive strength of 96.3 MPa for mortar specimens prepared from river sand and cured 80°C for 2 days. XRD results showed that quartz and aluminum sulfate hydrate remain unchanged during activation and this is the reaction between phosphoric acid and magnetite that results in the formation of an amorphous binding phase. The leaching test results showed a stabilization efficiency of 95.4% for manganese. All other elements showed leaching concentrations within the Chinese standard limits.

Moukannaa *et al.* (2018) investigated the possibility of incorporating a phosphate mine tailing called phosphate sludge (PS) into geopolymers. PS with a mineralogical phase composition of fluorapatite, quartz, calcite, dolomite, and a smectite clay mineral was incorporated into FA- and MK-based geopolymers at equal proportions (50% by weight). Using an experimental design based on response surface methodology, the effect of synthesis parameters (SH concentration, curing time and temperature) on density, water absorption and compressive strength of geopolymer paste specimens was studied. Results showed that incorporation of PS reduces the mechanical properties of the geopolymers. However, under optimum synthesis conditions (SH concentration of 12.5 M and a curing regime consisting of 24 h at 83.33°C and 13.50 days at ambient temperature) compressive strengths as high as 62 and 53 MPa were achieved for binary blends of FA/PS and MK/PS, respectively, confirming the possibility of recycling PS into geopolymers.

Sedira *et al.* (2018) prepared alkali activated binder using binary blends of tungsten mining waste mud (TMWM) with red clay brick waste (RCBW) as precursor and solution of SH and SS as alkali activator. Blends of higher RCBW content showed higher compressive strengths at all the tested ages. Paste specimens from binary blend of TMWM (50%)/RCBW (50%) cured at $60 \pm 2^\circ\text{C}$ for 24 h and then at laboratory conditions (20°C) exhibited the maximum 28-day compressive strength of 59 MPa. Studies by FT-IR spectroscopy and SEM/EDX confirmed formation of higher amounts of (N,C)–A–S–H and/or (N,K)–A–S–H gels in binary blends of higher RCBW contents.

Xia *et al.* (2019) studied the possibility of recycling hazardous lead-zinc smelting slag (LZSS) into a FA/GGBFS-based composite geopolymer for solidification and stabilization of its heavy metals (Pb, Zn, Cr and Cu). They firstly optimized the synthesis parameters of FA/GGBFS-based composite geopolymer for the highest possible compressive strength through single factor and orthogonal experiments. The optimum composition exhibiting the highest compressive strength of 47.39 MPa was used for solidification and stabilization of LZSS. Although incorporation of LZSS into composite geopolymer resulted in significant compressive strength loss, the reduced compressive strength (for example, 15 MPa for the blend incorporating 80% by weight LZSS), however, was still notable. In addition, the leaching test results were satisfactory and concentrations of leached heavy metals were far beyond the limits.

Conclusions

Recycling of aluminosilicate industrial wastes as precursor materials for geopolymer production is an important step towards sustainable waste management due to its significant environmental benefits including (1) alleviating the pressure due to land-filling expenses and environmental impacts, (2) the potential in reducing energy consumption and CO₂ emission (compared to the traditional Portland cement technology), (3) conservation of natural resources for binder production, and (4) effective immobilization of heavy metals present in aluminosilicate industrial wastes. Among different types of construction and demolition wastes and compared to concrete waste, brick, tile, and ceramic wastes show a higher potential for geopolymerization due to their higher reactive SiO₂ and Al₂O₃ contents providing suitable synthesis conditions including type, composition and dose of alkali activator and curing time and temperature. In some cases, incorporation of corrective materials such as OPC, GGBFS, metakaolin, etc., for compositional correction purposes contributes to higher degree of geopolymerization, which in turn improves the geopolymer properties significantly. Waste glass is highly deficient in its reactive alumina content and, therefore, incorporation of corrective materials rich in reactive alumina such as calcium aluminate cements, metakaolin, etc., is necessary. In contrast, red mud with its advantages of high alkalinity and ultrafine particles is highly deficient in reactive silica and, therefore, addition of corrective materials rich in reactive silica such as microsilica, GGBFS, etc., is required. Recently, tendency to recycle different aluminosilicate industrial wastes such as tungsten, gold, copper, and phosphate mine tailings into geopolymer material has increased not only for sustainable waste solidification purposes, but also for the effective stabilization of their heavy metal contents. In these cases, special consideration should be given to geopolymer soundness under water immersion condition. The published literature demonstrates the viability of recycling some of the most important aluminosilicate industrial wastes into value added products through geopolymerization technology as a sustainable and environmentally sound waste management method. Further research activities for characterizing appropriate aluminosilicate industrial wastes, improving the reactivity of the source materials by using appropriate corrective materials, optimizing synthesis and curing conditions, investigating soundness and durability performance of the geopolymer are required and will definitely contribute to the practical application of this technology.

Introduction

In a constantly evolving consumerist society, certain activities or initiatives become significant towards ensuring a sustainable development. Consequently, one of the most discussed issues in the contemporary time is the opportunities and challenges associated with 'recycling'. At the global level, there is an expanding effort on innovation and capacity building in recycling towards ensuring a closed-loop supply chain (Corder *et al.*, 2015). The recycling market could be 'considered as one of the key industries able to close the materials loop' (Cucchiella *et al.*, 2015: 264). This is imperative in an increasingly industrialized and urbanized world where quantity of waste generated observes a constant rise. With the linear economic models and the universality of the supply and demand, the aim of incessant growth is forecasted upon exhaustive use of energy and material in both the production and consumption phase (Wilson *et al.*, 2017). Resource depletion and waste generation have already been key apprehensions in several countries across the globe (Halvorsen, 2012). Managing the large volume of waste of different kinds and characteristics is particularly a major sustainability challenge today. The cities of the world are predominantly the sites of uncontrolled waste and pollution creation. For instance, in the year 2016 alone, the cities worldwide produced 2.01 billion tons of solid waste which is equivalent to a footprint of 0.74 kilograms per capita per day (World Bank, 2018).

It is essential to ensure country-specific reliable and detailed data on the generation of waste in order to confirm responsible waste management practices and policy initiatives. Several countries in the world lack such information, especially regarding toxic categories of waste such as electronic waste, biomedical waste, laboratory waste etc. As argued by Intharathirat *et al.* (2015:3), "In order to plan, manage and use municipal solid waste (MSW) in a sustainable way, accurate forecasting of MSW generation and composition plays a key role". Nevertheless, it is evident that the amount of waste generated globally, irrespective of the categories, is increasingly becoming alarmingly. As the generation of waste increases globally, the significance of recycling becomes both evident and imperative (Mueller, 2013). In order to address the global challenge of waste management towards sustainability, it is essential to initiate and ensure combined efforts from a range of public and private stakeholders (Xu *et al.*, 2018). It is because of the fact that, let alone individual researcher, no single discipline has the capacity to possess all the essential knowledge to maximize the increasingly multilayered waste management competence (Xu *et al.*, 2018).

With the rapid growth of population and urbanization, the waste generation is anticipated to upsurge by 70% from 2016's level to 3.40 billion tons in 2050 (World Bank, 2018). Accordingly, it is vital for the policymakers to decide the recycling practices to be implemented from the set of possibilities at their disposal in order to divert waste from the landfills (Mueller, 2013). Gradually, the world is acknowledging the importance of recycling towards avoiding detrimental environmental consequences. There are primarily three key benefits of recycling: environmental, economic benefits and public health and safety benefits (Kumar *et al.*, 2017). Describing the advantages of recycling of household solid waste, Nguyen *et al.* (2017:1–2) state:

"Essentially, recycling of household solid wastes is a cost-effective way of (a) efficiently utilizing landfill capacity; (b) minimizing the disposal of solid waste hence decreasing costs; (c) enhancing environmental quality; and (d) increasing socio-economic sustainability. Hence, encouraging recycling behavior is imperative, and should be prioritized especially in emerging markets, where rapid population growth, increased consumption, urbanization, and industrialization collectively cause a significant increase in solid waste generation by households. [...] the development of community recycling programs and the encouragement of participation by individuals in such programs are highly strategic, which requires comprehensive understanding of the motivations of those involved in recycling".

As there is a shift towards globalization and internationalization of knowledge creation, an increasing number of research institutes and scholars pursue their research external to their immediate surrounds (Xu *et al.*, 2018). This kind of initiatives lead to interdisciplinary, transdisciplinary and multidisciplinary research which is crucial for formulating and implementing responsible waste management policies and regulations including recycling.

In this article, we attempt to describe the regulations and policies regarding recycling, especially taking into consideration the case of electronic waste (E-waste) recycling policies in India. Electronic waste has been selected because it is one of the fastest growing waste toxic streams in the world today with immense recycling potential. First, we start with a basic description of electronic waste, followed by its potential as 'urban mines'. Understanding E-waste along with the concept of urban mines will provide the readers an idea about why E-waste recycling policies and regulations are imperative in the present-day scenario. This will act as a base for the article. We then explored the concept of circular economy where E-waste has the potential to contribute immensely. Essentially, urban mining and circular economy are two ideas on which effective recycling policies and regulations are highly focused on these days. Subsequently, we describe the current state of affairs associated with E-waste recycling policies in India. India is considered as a case because of the fact that although the country shares similar kinds of E-waste associated

challenges as that of China or many West African countries, it is yet to gain both attention and momentum in its research on E-waste (Borthakur and Singh, 2017a). Thus, our purpose is to provide a comprehensive overview on the E-waste recycling potential and evaluate how effective or ineffective the E-waste policies in India has been towards maximizing this potential.

Recycling Policies: Electronic Waste, 'Urban Mines', 'Circular Economy' etc.

A Brief Overview of Electronic Waste

Electronic waste (E-waste) is also acknowledged as Waste Electrical and Electronic Equipments (WEEE) and it has consistently been observed an increase in quantity across the globe especially during the two decades. Processing of E-waste is not only a rising concern but also a global challenge owing to an immensely huge volume generated worldwide (Dias *et al.*, 2018). Nevertheless, the exact volume of E-waste generated is a contested subject, both in the global and country-specific scale. For instance, in the context of India, it ranges from 480,000 tonnes of E-waste as estimated by a few researchers to 1.8 million tonnes as estimated by the Associated Chambers of Commerce and Industry of India (ASSOCHAM) in 2016 (Borthakur, 2017b). Such kind of disputed figures render it difficult for the researchers and policymakers to formulate effective policy responses or solutions. Yet, it is acknowledged that the quantity of E-waste generated in growing rapidly worldwide which calls for immediate interventions towards its effective management. Rapid growth in economy, progresses in information and communication technologies (ICT), advances in technological innovations, downward prices of electronic devices and increasing usefulness of most electronic equipments in the present-day context encourage a constant growth in the use of electronic and electrical equipments and generation of E-waste around the world (Borthakur and Govind, 2017c). Further, with advances in technology, automation has been accepted widely by the industries increasing the usage of electronic and electrical equipments (Kumar *et al.*, 2017).

E-waste characteristically comprises of precious and valuable materials as well as a number of hazardous constituents, which possibly could bring about environmental and economic advantages upon proper recycling (Dias *et al.*, 2018). Accordingly, recycling of E-waste is vital for numerous reasons. Firstly, the valuable and precious metal contents in E-waste has the potential to reduce the concerns and burdens associated with the natural mines. Secondly, appropriate E-waste recycling practices has the potential to minimize the environmental impacts of the hazardous constituents of E-waste. Nevertheless, E-waste disposal is inherently challenging and the involvement of the informal recycling sector without any environmental and human health considerations intensifies the challenges further. The arrival and ascendancy of the informal E-waste recycling units in countries such as India is a key concern as it includes practices (for example, acid-bathing to excerpt valued and reusable E-waste components) which are extremely perilous to the environment and human health alike (Borthakur, 2015). These informal operations involving shredding, open burning and incineration has the potential to release various toxic components present in electrical and electronic devices and create secondary pollutants such as dioxins along with lead, mercury etc. (Zeng *et al.*, 2018). There are further concerns associated with trade of E-waste (legal/illegal) where large quantities of E-waste are shipped from the developed to the developing countries. The informal E-waste recycling sector of the global south absorbs this waste sent by the global north. As argued by Davis *et al.* (2019:36):

"Over the past 20 years, informal electronic waste (e-waste) processing hubs in Asia and Africa have emerged as global sites of concern – icons of the dark side of globalization and the digital age. Drawing parallels to the outsourcing of manufacturing to overseas destinations where low labour costs and lax regulations allowed increased profits, NGO and media portrayals of e-waste hubs highlighted the poor working conditions and excessive pollution in these sites, which had become dumping grounds for the refuse of rich countries".

E-Waste as Urban Mines

Many researchers and policy experts argue that the increasing volume of E-waste in the developing world (produced both through domestic generation and illegal/legal import) could be considered as a good opportunity to industrialize the E-waste recycling sector and generate ample employment opportunities. Although there exist economic limits, complex electronics may contain up to 60 elements from the periodic table and several of these elements could be technically recoverable (see "Relevant Websites section"). The existence of precious metals such as gold (Au), platinum (Pt), silver (Ag), palladium (Pd), Gallium (Ga), tellurium (Te), tantalum (Ta), selenium (Se) and germanium (Ge) makes E-waste attractive for recycling (Khaliq *et al.*, 2014). There are other valuable metals such as copper (Cu), Aluminum (Al) and Nickel (Ni) present in E-waste. Recovering these precious/valuable metals extant in the E-waste stream as a part of what is known as 'urban mining' could be an attractive avenue for recycling (Zeng *et al.*, 2018). Describing 'urban mining' and its association with E-waste or WEEE, Cossu and Williams (2015:1, 3) state:

"Urban Mining extends landfill mining to the process of reclaiming compounds and elements from any kind of anthropogenic stocks, including buildings, infrastructure, industries, products (in and out of use), environmental media receiving anthropogenic emissions, etc. [...] The stocked materials may represent a significant source of resources, with concentrations of elements often comparable to or exceeding natural stocks. As for natural ores, extraction and processing of anthropogenic stocks is necessary and the generation of an economic benefit is essential. For these reasons, urban mining originally focused on electrical and electronic wastes (WEEE) which contain relatively high concentrations of expensive metals and rare earth elements [...] Whilst from an etymological point of view, it is clear that urban mining should refer to the exploitation of anthropogenic stocks, today the term is widely used for describing almost any sort of material recycling [...] WEEE is the backbone stream in urban mining as they concern critical raw materials of industrial interest".

An estimation by the United Nations University (UNU) suggests that the resource potential for secondary raw materials present in electronic waste is worth €55 Billion (See: *ibid*). It is, thus, indispensable to formulate and implement policies and regulations towards encouraging the idea of urban mining. Devising a comprehensive recycling policy is an essential first step here. Many countries have implemented stringent E-waste policies encouraging maximum recycling. However, these are predominantly the countries in the global North. The European Union has especially been a pioneer in this context implementing two important E-waste related directives: Restriction of Hazardous Substances (RoHS) and Waste Electrical and Electronic Equipments (WEEE) Directive. The RoHS Directive restricts the use of six substances: restrictions on the use of six hazardous substances i.e., lead, mercury, cadmium, hexavalent chromium and flame retardants such as polybrominated biphenyls (PBB) or polybrominated diphenyl ethers (PBDE). Among the developing countries, the Chinese government has actively been involved in creating an institutional and legislative framework to fulfill E-waste recycling (Yu *et al.*, 2010).

E-Waste and Circular Economy

As the concept of 'Circular Economy' began to attract attention globally against the widely dominant model of 'Linear Economy', E-waste became a major focus area. Differentiating the two concepts, Murray *et al.* (2017:371) argue:

"The term circular economy has both a linguistic and a descriptive meaning. Linguistically it is an antonym of a linear economy. A linear economy is one defined as converting natural resources into waste, via production. Such production of waste leads to the deterioration of the environment in two ways: by the removal of natural capital from the environment (through mining/unsustainable harvesting) and by the reduction of the value of natural capital caused by pollution from waste. Pollution can also occur at the resource acquisition stage. [...] By circular, an economy is envisaged as having no net effect on the environment; rather it restores any damage done in resource acquisition, while ensuring little waste is generated throughout the production process and in the life history of the product".

The concept of circular economy originated in the Europe. During the past 20 years, The EU has attempted to set the roots for the advance of a circular economy where waste is considered as resources and, consequently, utilized in a sustainable and efficient way (Cucchiella *et al.*, 2015). A flagship initiative towards resource efficiency was launched by the European Commission (EC) as the concerns associated with high commodity prices aroused and was first operationalized via the roadmap aimed at a resource efficient Europe (McDowall *et al.*, 2017). Subsequently, a wide range of policy actions recognized jointly as the 'Circular Economy Package' was announced which was later substituted by the 'Closing the Loop – An Action Plan for the Circular Economy' (McDowall *et al.*, 2017).

In the context of the developing world, China has taken commendable initiatives to ensure a circular economy. In the mid-2008, the Chinese People's Congress approved the Law for the Promotion of the Circular Economy, a national circular economy law (Mathews and Tan, 2011), which came into effect on 1 January 2009. As further described by Mathews and Tan (2011:437):

"The interest of the circular economy and its promotion in China lies in the fact that it has moved beyond an "environmental" concept to become a mainstream development goal [...] China's national leadership has clearly understood that continued development in the traditional linear manner, starting with resources taken from nature at one end and proceeding through production processes to the creation of wastes disposed in nature at the other end, is simply no longer feasible. It is destructive to the point of ruin, at both ends, and it is costly to both secure fresh resources all the time and lose resources in the form of waste: It is, in other words, both economically and ecologically inefficient [...] only in China has a circular economy been made the object of official development goals and been taken from the realm of environmental policy into the realm of development and economic policy – an extremely important step".

Recycling Policies: The Case of E-Waste Recycling Policy in India

India has a long past of recycling its waste ranging from papers, plastics, metals among many others. The E-waste recycling today constitute a major part of the country's recycling interventions. Similar to China and many other developing countries, E-waste is processed in India in small workshops or backyards using primitive processes such as open burning, strong acid digestion and manual disassembly and resulted in releasing a large amount of organic pollutants, hazardous acids and toxic metals into the immediate environment (Pradhan and Kumar, 2014). The study by Pradhan and Kumar (2014) further revealed uncontrolled informal E-waste disposal and recycling activities in the Mandoli industrial area in Delhi leading to higher levels of heavy metal contamination in groundwater, plants and surface soil. This is the story of majority of the key cities in the country. The dominance of the informal recycling activities in India, thus, calls for immediate policy attention towards averting both environmental and human health consequences. Nevertheless, addressing the concerns associated with recycling of E-waste in India is a tricky task. It is because of the fact that informal E-waste recycling activities in India is responsible for providing employment opportunities to a large number of urban poor as all the recycling associated activities like sorting, segregation, dismantling etc., are done manually in the informal recycling sites in the country (Borthakur, 2014). Further there are entrepreneurship opportunities involving low cost and other associated investments (Borthakur, 2014). The formalization of the informal sector may result in losing these employment and entrepreneurship opportunities for a section of the financially challenged mass of the country. Thus, a comprehensive E-waste management policy addressing the aspects of recycling in a local-specific way is one of the major needs in the country today.

In India, there was no regulatory framework on the management before the year 2011 which provided ample time for the unprecedented growth of E-waste in the country without appropriate management efforts. The economic liberalization policies in

India was unveiled in 1991 resulting the country emerged as one of the significant players in the global technology and outsourcing business (Sharma, 2015). The information technology and electronics sector in the country consequently observed a major boost with large volumes of consumer electronics heading to the Indian market. Although the IT revolution started in India way back in early 1990s, a proper policy related to E-waste was being introduced almost after 20 years, in 2011, in the form of the 'E-waste (management and handling) Rules, 2011' (Borthakur, 2016). This rule came into force from 1st May 2012. In the year 2016, there was an another, more exhaustive policy intervention in the form of 'E-waste (Management) Rules, 2016', enacted since October 1, 2017. While the number of registered E-waste recycling vendors has increased after the implementation of the E-waste rules in 2011 and 2016, the informal sector is still dominating the E-waste recycling businesses across the country. Moreover, the time period between formulation and implementation of policy in India is mostly much higher than that of the developed economies. The administrative delays in law enforcement are one of the major barriers in the implementation of policy measures in the country. In the year 2018, the Union Minister for Environment, Forest and Climate Change in India declared that the Government has amended the existing E-waste (Management) Rules of 2016 towards facilitating environmentally sound E-waste management in India (see "Relevant Websites section").

All the rules (2011, 2016 and 2018) associated with E-waste in India are based on the premises of Extended Producers Responsibility (EPR). The Organization for Economic Cooperation and Development (OECD) defined EPR as:

"Extended Producer Responsibility (EPR) is a policy approach under which producers are given a significant responsibility – financial and/or physical – for the treatment or disposal of post-consumer products. Assigning such responsibility could in principle provide incentives to prevent wastes at the source, promote product design for the environment and support the achievement of public recycling and materials management goals" (see "Relevant Websites section").

The first E-waste rule in the country ('E-waste (management and handling) Rules, 2011') did not set any collection target for the producers. The subsequent E-waste (Management) Rules, 2016 offered a number of rigorous alterations to the previous rules (Borthakur and Govind, 2017d). One among them is the setting up of stringent collection target. These targets were established in the rule as: (1) 30% (either by number or by weight) of the quantity of waste generation during the first two years of implementation of rules, (2) 40% during third and fourth years, (3) 50% during fifth and sixth years and (4) 70% during seventh year onwards (MoEF, 2016:22). Nevertheless, these targets proved to be too ambitious for the producers in the country and subsequently, the 'E-waste (Management) Amendment Rules, 2018' considerably lowered the existing collection targets especially for the starting year. As per this recent rules, "the phase-wise collection targets for e-waste in weight shall be 10% of the quantity of waste generation as indicated in the EPR Plan during 2017–18, with a 10% increase every year until 2023. After 2023 onwards, the target has been made 70% of the quantity of waste generation as indicated in the EPR Plan" (see "Relevant Websites section"). Overall, the constant formulation and amendment E-waste management rules in India since its inception in the year 2011 shows the complexity of the situation in the country and lack of adequate research before formulating possible management solutions. Thus, although E-waste in India has been observing a constant increase during the last two decades, the policy and regulatory measures associated with it is still at a very primitive stage (Borthakur, 2015).

On a positive note, a new economic instrument in the form of 'Deposit Refund Scheme' has been introduced in the 'E-waste (Management) Rules, 2016'. A deposit-refund system is "the surcharge on the price of potentially polluting products. When pollution is avoided by returning the products or their residuals, a refund of the surcharge is granted" (see "Relevant Websites section"). In a country where consumers expect a financial return for their recyclable waste, deposit-refund system could be a potential alternative and could aid in environmentally responsible consumer behavior. For instance, in return of some financial incentives, the local scrap dealers or kawariwalas collect most of the E-waste in the country from sources such as households, public and private sector businesses, academic institutions etc. (Borthakur and Govind, 2017c). A deposit refund system has the capability to encourage the already existent behavioral practices of the Indian citizens. It is, however, imperative to carefully ponder over how such a scheme could incorporate the actors in informal recycling sector. Nevertheless, Bhaskar and Turaga (2018) put forth that as India has no reference data on the amount of E-waste generated in the country, any quantitative evaluation of the Rules on outcomes, for instance, recycling or collection rates, is arduous. Further, the categories of E-waste are quite narrow and restricted in the country which includes only 21 varieties of electrical and electronic products as per the E-waste Management (Rules), 2016. Such restrictive definition results a confined effort of E-waste management practices and recycling initiatives in India.

Conclusions

In this article, we endeavoured to assess the regulations and policies regarding recycling taking reference to the situation of electronic waste (E-waste) in India. E-waste is selected owing to the fact that it is probably one of the most important streams of rapidly growing waste in need of immediate recycling interventions. As an emerging country and one of the largest generators of E-waste in the world, India provides an excellent case in this regard. We started with a general description of E-waste and its significance in relation to the concepts of urban mining and circular economy. Urban mining and circular economy are essentially two of the most talked about concepts in today's world towards ensuring effective resources recycling and thus, has implications in the context of E-waste. These two concepts largely decide major policy approaches in the current global scenario. Further, India's E-waste recycling policies has been discussed in detail with possible/existing challenges and opportunities.

Recycling of E-waste is vital, firstly because, the valuable, precious and rare-earth metal contents in E-waste has the potential to reduce the concerns and burdens associated with the natural mines. The concept of urban mining provides a good starting point here towards encouraging maximum resources recycling. Urban mining has the potential to encourage a circular economy involving least waste generation. Secondly, appropriate E-waste recycling practices has the potential to minimize the environmental impacts of the hazardous constituents of E-waste. The generation of E-waste is increasing rapidly and the trend is expected to continue during the near decades. Many researchers and policy experts argue that the increasing volume of E-waste in the developing world (produced both through domestic generation and illegal/legal import) could be considered as a good opportunity to industrialize the E-waste recycling sector and generate ample employment opportunities.

In India, E-waste recycling today constitute a major part of the country's recycling interventions. However, the recycling activities are dominated by the informal sector with intense detrimental repercussions to the human health and the environment. The first E-waste rule in the country is the 'E-waste (management and handling) Rules, 2011' which was followed by the 'E-waste (Management) Rules, 2016' and 'E-waste (Management) Amendment Rules, 2018'. The collection target under the 2016s rules had to be revised and reduced (at least for the initial years) in the 2018s rules. A new concept of deposit-refund system was introduced in the rules of 2016 which has the potential to aid in responsible collection and disposal facilities in the country. It is, however, imperative to carefully ponder over how such a scheme could incorporate the actors in informal recycling sector and how sustainable recycling could be ensured.

Overall, recycling associated regulations and policies are very much confined primarily in the developed countries with developing countries are yet to gain momentum in this regard. In the global south, China has taken commendable initiatives towards ensuring responsible recycling of its waste categories. India, although encounters similar E-waste problems as that of China, has a long way to go. India's E-waste recycling policies have gradually been taking shape and expected to result in positive outcomes in the near future. It is imperative that the world realizes the significance of recycling irrespective of the developed or developing countries so that sustainable development could be attained and healthy developmental activities could be ensured.

Recycling of Agricultural Waste for Wastewater Treatment

Rohini Singh, Sitarambhai Naranji Patel Institute of Technology and Research Centre, Bardoli, Gujarat, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

For the sustainable development, searching for novel green technologies for the pollutant abatement can be considered as an essential responsibility for the mankind to protect the environment and human health. Toxic pollutants get introduced to the aqueous effluent by means of various industrial activities viz. dyeing, mining and refining ores. Conventional methods for the removal of pollutants from contaminated aqueous solutions include physical, biological and chemical methods. The methods such as membrane separation, coagulation and chemical oxidation possess the major drawback of economic feasibility (Adegoke and Bello, 2015).

Agricultural waste materials are environmental friendly and exhibit potential biosorption capacity. Fig. 1 illustrates the overall preparation steps of agricultural waste to be utilised as an effective adsorbent for wastewater purification.

The major advantages of utilizing agricultural wastage as biosorbents as compared to the conventional methods for wastewater treatment include – (a) regeneration and recycling of biosorbents, (b) minimized sludge generation, (c) high efficiency and (d) low cost. Currently, attention has been focused towards the biological wastes collected as the by-products from large scale industrial operations and agricultural waste materials. Agro-waste contains loose and porous structure with functional groups such as the hydroxyl and carboxyl group that is responsible for their biosorption capacity (Dai *et al.*, 2018). The significant advantages of biosorption over conventional methods include: recycling of biosorbents, low cost, simultaneous waste management, high efficiency and minimization of chemical and biological sludge. Available literature reveals numerous agricultural waste materials viz. rice husk and bran, wheat husk and bran, saw dust of several plants, bark of the trees, coconut and ground-nut shells, waste tea leaves, jatropa deoiled cakes, apple, banana and orange peels, sugarcane bagasse, coffee beans, sugar beet pulp, Cassia fistula leaves, sunflower and cotton stalks, walnut shells and many more. The present article reviews the efficient and environmental friendly utilization of agricultural wastage for wastewater purification.

Mechanism of Wastewater Treatment Via Biosorption

According to the previous literatures, agricultural wastage consists of lignocellulosic materials with major structural component such as cellulose, hemicellulose and lignin. The overall mechanism of water purification via biosorption involves two phases – (1) solid phase or sorbent and (2) liquid phase or solvent. Affinity of pollutants dissolved in the solvents towards the specific sorbent acts as a driving force for an effective biosorption process. The entire process consists of several mechanisms that includes adsorption on surface and pores by physical forces or physisorption, chemisorption, complexation, ion exchange and chelation due to the driving force i.e., concentration gradient that results in effective diffusion (Sud *et al.*, 2008). Oxygen functional groups including ether along with carbonyl and hydroxyl groups bind heavy metal ions and various organic contaminants to the surface of adsorbents (Salleh *et al.*, 2011). Microorganisms are also capable of efficient absorption of water contaminants such as heavy metal in both live and dead conditions. Various microorganisms include fungi, bacteria, yeast and algae. Biosorption of metals is a complex process that depends upon various parameters such as type and state of biomass, binding capacity of the biomaterials, metal's chemical properties along with the operating conditions such as temperature, pressure and pH (Javanbakht *et al.*, 2014).

Performance of Agricultural Waste Materials as Biosorbents for Wastewater Treatment

Agroindustry residues are considered as ecologically safe and inexpensive adsorbent that requires comparably less pre-processing. Moreover, utilizing agro-waste as the substitute to conventional products possess both environmental and economical benefits.

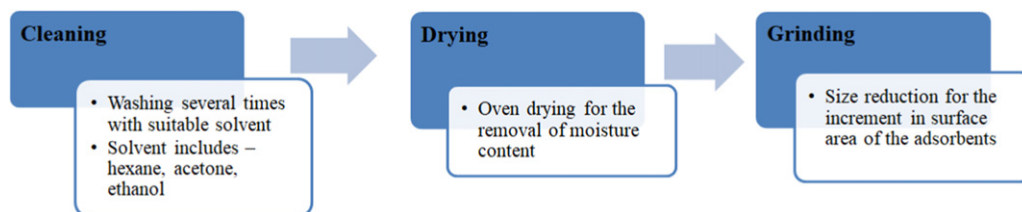

Fig. 1 Overall preparation steps of agricultural wastage to be utilised as adsorbents.

Rice Husk

Rice husk can be considered as an effective agro waste obtained from rice mills as a by-product. Rice husk ash has been mentioned in numerous literatures as an efficient adsorbent for wastewater treatment. The overall characteristics of rice husk ash depend on various factors such as – method of preparation, sources and combustion technologies (Prasara-A and Gheewala, 2016). Silica rich rice husk is an abundant waste biomass, capable to purify gas, soil and wastewater via integrated processes, adsorption and catalysis (Shen, 2017). **Table 1** summarises the research work performed for wastewater purification via effective utilization of low cost rice husk.

Saw Dust

Saw dust had been successfully studied by several researchers as a low cost adsorbent. Based on the experiments conducted, higher initial concentration and lower temperature were proved as favourable factors for the adsorption of pollutants. In addition to that, stirring speed plays an essential role in the acceleration of the overall performance of saw dust as adsorbent whereas, intraparticle diffusion hinders the adsorption rate (Dutta *et al.*, 2001). **Table 2** listed the utilization of waste saw dust for the wastewater purification.

Banana Waste

Based on the recent literatures banana wastes acts as a highly efficient adsorbent against hazardous environmental pollutants that includes organic pollutants, heavy metals and pesticides. Chemical modification is essential for the effective utilization of banana waste derived low cost adsorbent (Ahmad and Danish, 2018). **Table 3** mentioned numerous research work executed worldwide via effective application of banana peel as biosorbents.

Sugarcane Bagasse

Sugarcane bagasse prepared as an agro–agro waste can be utilised as an efficient substitute of activated carbon for the decontamination of various hazardous pollutants. Numerous pre-treatment and chemical modification methodology have been resea-

Table 1 Summary of research done by the various researchers utilizing low cost rice husk as agricultural waste material for wastewater treatment

Agricultural waste	Pollutants	Performance (%)	Reference
Rice husk (1 g at 42 mesh to 20 mL of milk)	Aflatoxins	100	Scaglioni and Badiale-Furlong (2016)
Mixture of 5, 10 and 15 % rice husk and raw sludge	Rosaniline dye, metallic cations, chlorine	100 (Rosaniline dye in 800 min.)100 (Ni(II) and Pb(II) in 600 min.)100 (chlorine in 1000 min.)	Shalaby <i>et al.</i> (2017)
Polypyrrole and rice husk ash nanocomposite	Heavy metals, anions and COD from textile wastewater	Upto 95.1 (at 5, 10, 15, 20 and 25 min.)	Ahmed and Reyad (2017)
Rice husk ash (upto 50 g/L)	Rice mill wastewater	Upto 70 (120 min)	Kumar <i>et al.</i> (2015)
Rice husk ash (10 g/L)	Rice mill wastewater	48.1 (120 min)	Kumar <i>et al.</i> (2016)
Rice Husk Ash (2 g/L)	Phosphate	89 (120 min)	Mor <i>et al.</i> (2016)

Table 2 Summary of research done by the various researchers utilizing low cost saw dust as agricultural waste material for wastewater treatment

Agricultural waste	Pollutants	Performance (%)	Reference
Saw dust blended with MgO agglomerates	Borate	760 mgB/kg (10 h)	Sasaki <i>et al.</i> (2011)
Eucalyptus wood (Eucalyptus globulus) saw dust (SD)	Congo red	Upto 95 (4 h)	Mane and Vijay Babu (2013)
Polyaniline coated on sawdust	Cd (II) ion	Upto 100 (20 min)	Mansour <i>et al.</i> (2011)
Saw dust	Zn(II) and Cd (II) ions	Upto 90 (320 min)	Naiya <i>et al.</i> (2009)
Polyacrylamide grafted rice (Oryza sativa) husk and (Tectona grandis) saw dust	Cd ²⁺ ions	Upto 85% (3 h)	Sharma <i>et al.</i> (2009)
Biochar derived from eucalyptus saw dust modified with citric, tartaric, and acetic acids	Methylene blue	178.57, 99.01, and 29.94 mg/g for citric, tartaric, and acetic acids respectively	Sun <i>et al.</i> (2015)

Table 3 Summary of research done by the various researchers utilizing low cost banana peel as agricultural waste material for wastewater treatment

Agricultural waste	Pollutants	Performance (%)	Reference
Banana corm activated charcoal	Mercury (Hg)	5 gm/l (1 ppm Hg)	Marichelvam and Azhagurajan (2018)
Banana peel powder	Rhodamine-B	Upto 81.07 % (0.4 g/30 mL, 25 mg/L Rh- B)	Singh <i>et al.</i> (2018)
Chemically modified banana peels	MB and Co(II)	1303.54 (MB) and 122.39 (Co(II)) mg/g	Yu <i>et al.</i> (2018)
Chemically modified banana peels	hexavalent chromium Cr(VI)	96 % (4 g/L, 400 mg/L- Cr in 120 min)	Ashraf <i>et al.</i> (2017)
Chemically modified banana peels	Mn(II)	94 % (4 g/250 mL)	Ali <i>et al.</i> (2016)
Banana peels powder (BPP)	Sr(II)	41.5 mg/g	Mahindrakar and Rathod (2018)
Banana peels nanosorbent	actinides (uranium and thorium)	27.1 mg/g, 34.13 mg/ g for uranium and 45.5 mg/g, 10.10 mg/ g for thorium in synthetic and real mine water	Oyewo <i>et al.</i> (2016)
Activated Surface of Banana Peels	Reactive Red Dye (RRD)	70.25% (1 g/100 mL)	Temesgen <i>et al.</i> (2018)

Table 4 Summary of research done by the various researchers utilizing low cost sugarcane bagasse as agricultural waste material for wastewater treatment

Agricultural waste	Pollutants	Performance (%)	Reference
Sugarcane bagasse cellulose mixed esters	Co ²⁺ and Ni ²⁺	0.62 and 0.53 mmol/ g for Co ²⁺ and Ni ²⁺ , respectively	Elias <i>et al.</i> (2019)
Sugarcane bagasse (SCB)	cadmium (Cd(II))	24.47 mg/g	Li <i>et al.</i> (2018)
Sugarcane bagasse	nickel (II) ions	2 mg/g	Alomá <i>et al.</i> (2012)
Maleic anhydride grafted sugarcane bagasse	methylene blue	82 mg/g (98%)	Ge <i>et al.</i> (2017)
Sugarcane Bagasse	mercury ions	35.71 mg/g	Khoramzadeh <i>et al.</i> (2013)
Wood sawdust and sugarcane bagasse modified with EDTA dianhydride (EDTAD)	Zn ²⁺	105 mg/g	Pereira <i>et al.</i> (2010)
Sugarcane bagasse	mercury ions	178 mg/g	Sun <i>et al.</i> (2018)
Immobilized sugarcane bagasse	Cr(VI) and Cr(III)	80.6% and 41.5% respectively	Ullah <i>et al.</i> (2013)
Sugarcane bagasse biochar	Malachite green dye	3000 mg/L	Vyavahare <i>et al.</i> (2018)

ched worldwide for the synthesis of low cost biosorbent (Saad *et al.*, 2010). **Table 4** summarises the application of low cost sugarcane bagasse as agro waste for wastewater purification.

Categories of Contaminants

Inorganic Pollutants

The expeditious advancement of urbanization and industrial development resulted in the contamination of inorganic pollutants such as heavy metals and non-metal including nitrogen and phosphorous. Heavy metals including arsenic, copper, lead, cadmium, nickel and many more possess detrimental effect on human as well as aquatic life.

Organic Pollutants

Organic pollutants mainly dyes, antibiotics, pesticides, aromatic compounds and oil spills have been considered as an emerging organic contaminants. Nowadays, the utilization of agro waste as adsorbents in wastewater purification has gained global attention by the researchers. As illustrated in previous sections, removal of hazardous pollutants via agricultural wastage facilitates economical and environmental friendly methodology for wastewater purification. **Fig. 2** illustrates various categories of contaminants that could be removed via agro wastage.

Adsorbent Recycling

Regeneration of adsorbent promotes solid waste management and improves the economy of wastewater purification phenomena. Numerous adsorption methods include thermal degradation of pollutant, biological methods and solvent extraction. Thermal degradation

Fig. 2 List of contaminants.

method for the regeneration of the adsorbent involves calcination of the treated adsorbents with the pollutants adsorbed on the surface. During calcination at a suitable temperature for certain duration, thermal degradation of the pollutant occurs and the treated adsorbents can be reused. Before calcination, the information regarding the thermal behavior of the pollutant and adsorbent must be gathered via thermogravimetric analysis. Biological methodology utilizes certain microorganisms to desorb the treated adsorbent and considered as an environmental friendly and facile treatment. After successful desorption, regenerated adsorbent can be reused. Moreover, appropriate solvent must be selected for the efficient regeneration of the contaminated adsorbent via solvent extraction process.

Future Aspects

Utilizing or recycling of agricultural wastes for wastewater treatment exhibits dual advantages i.e., solid waste management and pollutant abatement. According to the recent analysis, China is the leading country in the production of agricultural waste (Dai *et al.*, 2018). Untreated agro-waste is majorly responsible for rural environmental pollution. Therefore, enhanced reuse of agricultural waste can efficiently reduce air pollution along with the remediation of wastewater contaminants. Based on the various literature studies, agricultural wastes can be considered as an ideal choice to deal with the persistent harmful water contaminants. For achieving enhanced efficiency, appropriate modifications to improve the adsorption capability of the agricultural waste should be conducted. Therefore, the future scope of efficient utilization and recycling of agricultural waste materials as adsorbent includes development of economically modified agro-waste and effective usage in order to deal with the wastewater treatment.

Conclusions

Agriculture based biomass exhibits the capability to replace expensive commercial adsorbents such as activated carbon for wastewater treatment. Several low cost and recyclable adsorbents derived from agricultural wastage are increasingly researched worldwide. It possess dual applicability i.e., wastewater purification and solid waste management. However, selection of the agricultural waste plays a major role in the adsorption of persistent harmful contaminants. The adsorption efficiency of porous agro based adsorbent with or without proper chemical modification gets effected by various factors such as adsorbent dosage, pH and temperature. The intention of the present article is to develop global awareness amongst the researchers to utilize the agricultural wastage for an economical wastewater purification and spontaneous solid waste management.

Recycling of Construction and Demolition Wastes Into Renewable Construction Materials

Soon P Yap, Yingxin Goh, Kim H Mo, and Hussein A Ibrahim, University of Malaya, Kuala Lumpur, Malaysia

© 2020 Elsevier Inc. All rights reserved.

Background of Construction and Demolition Wastes (CDW)

Construction and demolition wastes (CDW) could be broken concrete, bricks from buildings, or broken pavements and these CDW are produced every year at huge quantities. The construction industry is a major generator of several types of CDW. Old buildings approaching the end of their lives are demolished producing millions of tons of concrete wastes, large quantity of rejected construction products for non-compliance with the required specifications, as well as marble deposits provided a large quantity of aggregates of different sizes induced by fragmentation operations, sawing of large stones, and processing plants proliferate a very large quantity of wastes consisting mainly of powders and sludge (Belachia and Hebhoub, 2018). Most of the CDW came from demolition process while minor portions (around 10%–30%) are generated during the construction process (EPA, 2018; Ning, 2017).

The total amount of CDW generated in different regions are shown in Table 1. In South East Asia countries such as Malaysia and Thailand, about 28.34% of the annually generated solid waste comes from construction and demolition waste. The Malaysian construction demolition waste generation estimation was 161.2 tons per day in 2009 and has increased to 299.69 tons per day in 2015. The waste generation is projected to reach 368.31 tons per day by 2023 (Fauziah and Agamuthu, 2003). Meanwhile, the rapid development in China also produced a massive production of CDW of 1255.6 million tons in 2013, but soon to increase by 28.5% within 4 years to 1613.3 million tons in 2016 (Ning, 2017). On the other hand, in Europe, more than 25% of total waste comes from the demolition or renovation of buildings, and half of this waste clutters landfills. It is estimated that only 30% of the materials used are currently recycled, though the practice in some European countries shows that 90% of the wastes is recyclable. According to Eurostat the total amount of waste generated in the European Union, was over 2.5 billion tons, of which almost 860 million tons belonged to construction and demolition activities (Bravo *et al.*, 2015).

Due to the massive amount of CDW generated every year and these CDW are basically non-degradable, CDW often get sent to landfills or dumped illegally, raising major concerns in terms of environmental sustainability (Yap *et al.*, 2018). CDW is often considered as a nuisance to construction industry and environmental agencies in all countries. Hence, the sustainable solution to recycled CDW including recycled concrete aggregates (RCA) and recycled marble (RM) as alternative construction materials has become a global trend nowadays with the following advantages:

- (1) To eliminate CDW by recycling and reuse, hence protecting the environment;
- (2) Help to solve some problems related to material scarcity. For example, some countries are constantly facing difficulties to source good quality aggregates such as granite;
- (3) To preserve our natural resources that are not infinite, and depleting rapidly due to the vast development of construction industry particularly in developing countries;
- (4) Reducing the landfill areas as some of the cities are suffering from land scarcities;
- (5) Giving a second life to our renewable and recyclable wastes (Fauziah and Agamuthu, 2003);
- (6) Lowering the consumption of raw coarse aggregates, which then leads to reduction in costs, energy and pollution associated with the raw material extraction and transport (Yap *et al.*, 2018).

This article will then focus on one of the sustainable solutions to handle the CDW, which is the recycling of concrete wastes into recycled concrete aggregates (RCA), as well as recycling of marble wastes into recycled marble (RM).

Table 1 Summary of construction and demolition wastes generation in 2015 according to different regions

Country	CDW (million tons)	References
Malaysia/Thailand (Region: South East Asia)	299.69	Fauziah and Agamuthu (2003)
European Nations (Region: Europe)	860.00	Yap <i>et al.</i> (2018)
United States of America (Region: North America)	547.80	EPA (2018)
China (Region: Asia)	1533	Ning (2017)
India (Region: Asia)	23.75	Arora and Singh (2018)
Algeria (Region: Africa)	15	Belachia and Hebhoub (2018)

Properties of CDW

Recycled Concrete Aggregates (RCA)

Recycled concrete aggregates (RCA) are recycled from the crushing process of demolished concrete to regain the original aggregates (Fig. 1(a)). This recycling process is essential in some of the countries where good aggregates are lacking. The most significant difference between RCA and natural coarse aggregate is the presence of mortar. The RCA normally consists of the natural coarse aggregates (NA) surrounded by a layer of adhered mortar of source concrete, as shown in Fig. 1(c). The adhered mortar being old, contains hydrated, unhydrated cement particles and sulfate. The presence of such mortar will then form a weak porous layer, influencing the strength and structural performance of the recycled coarse aggregate (Etxeberria *et al.*, 2007).

When compared to natural aggregates, the physical and mechanical properties of RCA are generally lower, as shown in Table 2. As seen from Table 2, the bulk densities of RCA and normal aggregates differ by about 7%–17%. It can be explained that the density of adhered mortar is less than the underlying aggregates when compared to normal aggregates (Arora and Singh, 2018). Also, RCA have 6 times higher porosity than normal aggregates due to the adhered mortar on the surface of RCA and their high porous nature leads to an increase in the water absorption capacity. The water absorption capacity usually ranges up to 8% for RCA (Poon *et al.*, 2004). As mentioned, the strength of concrete with RCA is directly proportional to the strength of RCA. By referring to

Fig. 1 (a) Recycled concrete aggregates, (b) granite aggregates, and magnified surfaces of (c) RCA and (d) natural granite aggregate. Reproduced from Yap, S.P., Chen, P.Z.C., Goh, Y., *et al.*, 2018. Characterization of pervious concrete with blended natural aggregate and recycled concrete aggregates. *Journal of Cleaner Production* 181, 155–165.

Table 2 Physical properties of recycled concrete aggregates and natural aggregates

Physical properties	Recycled concrete aggregates (RCA)	Natural aggregates	References
Bulk density (kg/m^3)	2330–2394	2620.1–2890	Katkhuda and Shatarat (2017); Yap <i>et al.</i> (2018); Arora and Singh (2018); Poon <i>et al.</i> (2004)
Porosity (%)	10.45	1.60	
Water absorption (%)	6.28–8.05	1.25–3.50	
Specific gravity	2.32	2.65–2.67	
Aggregate impact value (%)	5.28	1.67	
Aggregate crushing value (%)	24.5	15.4	
Los Angeles abrasion value (%)	10.30	10.17	

Table 2, the aggregate impact value, aggregate crushing value and Los Angeles abrasion value of RCA are much lower compared to normal aggregates. This indicates that RCA has a lower impact, crushing and abrasion resistance due the higher tendency of adhered mortar loss under different loadings. Hence, the existing mortar on RCA is always advised to be removed to reduce the discrepancy when conducting aggregate testing and concrete production.

Three common methods that are used to treat RCA is (i) Acid Treatment Method, (ii) Mechanical Treatment Method, and (iii) Thermal treatment method.

- (1) [Katkhuda and Shatarat \(2017\)](#) reported the procedures for acid treatment of RCA. The acid method involves soaking of RCA in acidic solution (range of acid concentration is 0.1–1 M) for 24 h. After 24 h of pre-soaking, the aggregates were washed in normal water to rinse off the adhered mortar and then the RCA is dried. In this treatment, the amount of mortar that remains adhered to the coarse aggregate was 2%. The water absorption recorded for untreated RCA is 4.58% and specific gravity is 2.58. The water absorption of acid treated RCA is 3.10%, which was 40% lower than that of untreated RCA and the specific gravity is 2.47, which was 5.4% higher than untreated RCA. The Los Angeles abrasion resistance of acid treated RCA concrete was found to be 29.5% of normal aggregate concrete, which was 1.5% better than the untreated RCA concrete.
- (2) [Babu et al. \(2015\)](#) reported the procedures for mechanical treatment of RCA. The RCA was treated in Los Angeles abrasion machine for 300 revolutions. Then the RCA was sieved in a 4.75 mm sieve. The amount of mortar that remains adhered to coarse aggregate after treatment is 5%. For this treatment method, the water absorption of mechanical treated RCA is 3.1%, 32.3% lower than that of untreated RCA and specific gravity is 2.54, 3.5% higher than untreated RCA. Compared to normal aggregate concrete, the bond strength of mechanically treated RCA is 11.37 MPa, which was 90% of the control sample.
- (3) [de Juan and Gutiérrez \(2009\)](#) reported the procedures for thermal treatment method. The RCA was first treated thermally at 500°C for 2 h in a furnace. After 2 h, the RCA is immediately immersed in water. The sudden change in temperature of RCA removes the mortar from the surface of aggregate. The aggregate was then given a little mechanical stress by using hammer, followed by washing, drying and crushing into required size. In this treatment, the amount of mortar that remains adhered to coarse aggregate is 11%, which is less effective compared to the other two techniques mentioned above. The water absorption of thermal treated RCA is 3.8%, 17.0% lower than that of untreated RCA and specific gravity is 2.51, 2.4% higher than untreated RCA.

From this review, the effective treatment methods of RCA are acid and mechanical treatment. However, the cost and time consumption required has rendered its use less economical. Thus, the justifications on the necessity to treat the RCA should be based on the economic benefits of applied RCA and improvement in efficiency.

Recycled Marbles

Marble is a metamorphic rock containing large amount of calcium carbonate and small amounts of silica, feldspar, iron oxide, mica and fluorine ([Topçu et al., 2009](#)). Recycled marbles (RM) is an inert material that is produced as the marble industrial by-product throughout sawing, sprucing, shaping and polishing of marble ([Fig. 2\(a\)](#)). Similar to other CDW, the common practice to handle the marble wastes is the disposal and storage in open areas, as shown in [Fig. 2\(b\)](#).

Marble wastes are available in the forms of marble dusts as well as marble fine and coarse aggregates ([Fig. 3](#)), depending on the sizes of the marble wastes. The marble dusts generally have particle size of $< 150 \mu\text{m}$, while the size of marble aggregates ranges between $150 \mu\text{m}$ and 20 mm. Marble dust is an inert powdered by-product from marble processing and these dust can make up to

Fig. 2 (a) Marble processing in factory; (b) Disposal of marble wastes in open areas. Reproduced from Li, L.G., Huang, Z.H., Tan, Y.P., Kwan, A.K.H., Chen, H.Y., 2019. 2% of overall marble wastes. Marble dusts can be a reason of a heavy downside to the surroundings as these fine particles are released the atmosphere directly (Gurcharan and Madan, 2017). Among the marble wastes, marble dust (also called sludge, an agglomeration of water and very fine particles produced by cutting the stone) is the most widely studied alternative, primarily because it is quite versatile (André *et al.*, 2014). In some reports, marble fine aggregates were also considered as marble dusts, as both serve the same purpose as filler material in concrete. However, this article differentiates between the marble dust and marble fine aggregates because marble dusts are typically used as filler material to replace cement, while marble fine aggregates are substitution materials for sand. Meanwhile, there is little information on the potential use of larger marble waste as a coarse aggregate.

Table 3 shows the comparison of chemical compositions of marble wastes with natural aggregates and cement. The main components in marble wastes are calcites (CaCO₃), along with other minerals. It should be noted that there is a high amount of CaO in marble wastes (~33%–55%), which is comparable to cement. This is the reason why marble dusts are widely used as filler materials to replace cement in cement research, and this will be further discussed in Section “Concrete Properties Incorporating CDW”. Finally, the loss on ignition (LOI) in marble wastes are as high as 45% while both aggregates and cement have low LOI of > 5%. This phenomenon is due to the high carbonates content which is due to the dissociation of CaCO₃ and dolomite (CaMg(CO₃)₂) that partially transform themselves into carbon dioxide gas (CO₂) at temperatures higher than 750°C.

Meanwhile, Table 4 shows the physical properties of all forms of marble wastes. The noteworthy property is the lower abrasion resistance in recycled marble wastes compared to conventional aggregates, which will eventually result in lower mechanical properties of concrete incorporating recycled marble aggregates. However, the value remains acceptable as it is still lower than 50%, which is the maximum recommended for incorporation in structural concrete (André *et al.*, 2014).

Concrete Properties Incorporating CDW

Recycled Coarse Aggregates (RCA)

In most of the research on recycled coarse aggregates (RCA), there is a common observation obtained, which is the strength reduction in concrete with coarse aggregate replacement by RCA up to 100%. In the work done by Poon *et al.* (2004), the concrete

Table 4 Physical properties of recycled marble wastes

Marble wastes	Properties	Value	Comparison	References
Marble dust	Bulk density (kg/m ³)	2.684	–	Hebhoub <i>et al.</i> (2011)
	Porosity (%)	1.96	–	
	Water absorption (%)	0.39	–	
	Wear resistance (mm)	1.82	–	
	Impact resistance (cm)	40	–	
Marble coarse aggregate	Loose bulk density (kg/m ³)	1352	1350 (Granite aggregate)	André <i>et al.</i> (2014), Kore and Vyas (2016)
	Porosity (%)	49.7	50.1 (Granite aggregate)	
	Specific gravity	2.70	2.61 (Natural aggregate)	
	Water absorption (%)	0.05–0.66	0.54–1.08 (Natural aggregate)	
	Los Angeles abrasion value (%)	34.87–38.8	25.88 (Natural aggregate)	
Marble fine aggregates	Specific gravity	1.67	1.72 (Sea sand)	Belachia and Hebhouh (2018)

Fig. 4 Micrographs on crack propagations in (a) normal aggregate and (b) RCA fractured specimens. Reproduced from Yap, S.P., Chen, P.Z.C., Goh, Y., *et al.*, 2018. Characterization of pervious concrete with blended natural aggregate and recycled concrete aggregates. *Journal of Cleaner Production* 181, 155–165.

made with RCA shows up to 30% loss in compressive strength for 100% coarse aggregate replacement. For the strength reduction, contradict explanations had been proposed by different researchers. For instance, Barnhouse and Srubar (2016) proposed that the RCA consumed higher paste volume due to the adhered mortar which substantially reduced the strength of RCA concrete. On the other hand, Poon *et al.* (2004) explained the strength reduction was attributed to the poor bonding between aggregate and cement paste. Yap *et al.* (2018) has proven the latter was the contributor to the weaker mechanical properties in RCA concrete through microstructural characterizations. By referring to Fig. 4, both RCA and normal aggregate concretes showed different crack propagation paths. In RCA specimen (Fig. 4(b)), it was observed that the crack displays less branching, while failure plane of normal aggregate specimen showed more crack branching and direction diversion (Fig. 4(a)). A branched crack propagation often results in higher compressive strength concrete as more energy is required to cause failure.

In order to compensate the strength reduction, Etxeberria *et al.* (2007) suggested that for RCA replacement between 50%–100%, the water to cement ratio should be lowered by 4%–10% to obtain the same compressive strength as control concrete. Similar behaviors are also noticeable in tensile strengths of RCA concrete at which 10%–15% reduction in both splitting tensile and flexural strengths (Arora and Singh, 2018).

Other researches on RCA concrete can be summarized as below:

- According to the study from Yap *et al.* (2018), it was revealed that the modulus of elasticity of pervious concrete with RCA increases with higher RCA content. However, they explained that this result may not be convincing because when RCA content increases, lesser aggregate-cement paste bonding was found in RCA mixes compared to the normal aggregate mixes, and the increase in modulus of elasticity was due to the premature failure of RCA specimens under compression loading. The cause of the premature failure was suggested to be due to the preferred failure path along the adhered mortar as discussed before. On the other hand, RCA replacement showed positive impact on the concrete when mixes containing high RCA content showed lower brittleness ratios.
- In another study, Ajdukiewicz and Kliszczewicz (2002) reported that the bond strength of RCA can be more than the conventional concrete. In this study, it was found that when recycled aggregates from high strength concrete were used, the

compressive strength can be similar or even higher than for comparable normal. However, there are indication that the bond strength of natural aggregate were 9.4%–21.3% higher than RCA concrete (Pandurangan *et al.*, 2016). Such contradictions in results may have attributed to the type of bond test used. If the results are closely analyzed, it could be seen that the performance of RCA in bond tests is found to be good if pullout specimens are used for determination of bond strength. This is because the effect of adhered mortar and shape of RCA is not captured effectively in pullout tests (Pandurangan *et al.*, 2016).

- Furthermore, when 30% of natural aggregate was replaced with recycled coarse aggregate, it is found that there is no significant influence on the compressive strength. However, when the recycled coarse aggregate is used to fully replace the natural aggregate, the compressive strength for the aforementioned mix was only 30% of the 100% natural aggregate mix. As for the 28-days compressive strength of concrete replaced with 100% of recycled coarse aggregate, it has the strength of 77% conventional concrete (Pandurangan *et al.*, 2016).

Recycled Marbles

As mentioned afore, the researches on recycled marbles mainly focus on the recycling of marble dust as marble dust are more versatile as a filler material to replace cement, due to the high CaO content in marble wastes. In other hand, cement replacement is the most economical and sustainable approach to recycle the wastes materials as cement is the most expensive component in concrete, as well as the cement hydration process is the main contributor of carbon dioxide gas. Based on the literature, the optimum content of marble dust in concrete/mortar is up to 15% without showing any depreciation in concrete strength (Gurcharan and Madan, 2017). Some examples of the research on recycling marble dusts to replace cement are:

- Topçu *et al.* (2009) investigated the potential of marble dust as filler materials in self-compacting concrete and they concluded that maximum cement replacement up to 200 kg/m³ with marble dust was feasible, without affecting the fresh properties of self-compacting concrete. Also, the filling effect of the marble dust showed good potential to reduce the void content in the concrete.
- In addition, in the asphaltic concrete, the use of marble dust also showed positive effects in the design of bitumen mixes by Marshall Method (moisture susceptibility, static creep, flexural fatigue, and wheel-tracking tests) as compared to different fillers such as fly ash and granite dusts.

Meanwhile the examples of researches on the recycling marble wastes to replace concrete's coarse and fine aggregates are shown below:

- Hebhouh *et al.* (2011) reported the high potential of using wastes from marble as an alternative of natural aggregates (coarse and fine) in concrete production. Experimental research was designed on three groups of concrete mixtures: (i) fine aggregate substitution, (ii) coarse aggregate substitution and (ii) substitution of both aggregates. The outcomes showed that the mechanical properties of concrete samples were good and utilization of the marble wastes were found to adapt to the concrete production standards.
- Results from Kore and Vyas (2016) showed that, marble aggregate can be used to improve the mechanical properties of conventional concrete mixes (up to 80% replacement of coarse aggregate) with no adverse effect against acid attack. However, one of the side effects of incorporating recycled marble aggregates was a 26%–83% hike in permeability/depth of water penetration.
- In another study from André *et al.* (2014), replacement of coarse aggregates with marble aggregates produced comparable results in terms of workability, density, water absorption, carbonation depth but the incorporation of coarse marble aggregates in the mixes resulted in a significant increase of the chloride migration coefficient. The low alumina percentage of these aggregates may be the primary cause, as this compound promotes the formation of tricalcium aluminate, which favors the fixation of the chloride ions.
- Finally, on recycled marble fine aggregates, the study conducted by Belachia and Hebhouh (2018) concluded that recycled marble sand retarded the hardening at a young age. Since the sand is coarse, it does not return quickly in the hydration reaction of the cement.

Applications of CDW (Structural and Non-structural)

Based on the discussions in the Section "Concrete Properties Incorporating CDW", it was known that CDW can be converted into recycled concrete aggregates (RCA) as well as recycled marbles (RM) in the forms of marble dusts, marble coarse aggregates and marble fine aggregates. RCA can be used to fully replace conventional natural aggregates, however, the replacement may be associated to depreciation of concrete properties. Meanwhile, marble dusts had been utilized as fillers to replace cement, up to the amount of 15%. Finally, both marble fine and coarse aggregates had been proven as good substitution of conventional concrete aggregates without significant effects on strength, durability and workability. Judging from these advantages, both RCA and RM had been applied in different structural and non-structural applications, with the following examples:

- Due to the lower strength in RCA concrete, RCA mainly finds its applications in the pavement of roads, landfills and low grade concrete structures (Pandurangan *et al.*, 2016);
- Also, since the pavement blocks which requires low strengths, another famous non-structural application of RCA is as pavement blocks and pedestrian paths (Poon and Chan, 2006);

- For marble dusts, there is a way to reduce the cost and carbon emissions of cement, at which marble dust is mixed in Portland cement clinker at different ratios and the results were positive that 10% of marble dust did not affect the setting time, specific surface area but higher compressive strength. This eventually reduce the environmental problem directly related to human health and wellbeing (Aruntas, *et al.*, 2010);
- Buyuksagis *et al.* (2017) examined the accessibility of marble powder additional substance at numerous proportions instead of dolomite, which is the crude material in glue mortars of insulation board. The employment of marble powder with dolomite was also investigated economically and it had been observed that it is economical advantageous to form price calculations and in accordance with the relevant EN standards;
- Since the values obtained in the Los Angeles abrasion test are within the limits as per BIS: 2386 (part IV) – 1963, the marble aggregates can be used in concrete pavement works (Kore and Vyas, 2016).

The applications of RCA and RM are not limited to the applications described above. It is believed that with the proper design and treatment methods, the CDW can be utilized in construction industry, to produce green and sustainable concrete products, which will then reduce the carbon footprints of the concrete produced.

Recycling of E-Waste

Anwesha Borthakur, Leuven International and European Studies (LINES), KU Leuven, Leuven, Belgium

Pardeep Singh, Department of Environmental Studies, PGDAV College, University of Delhi, New Delhi, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

Electronic waste, commonly known as 'E-waste', is a rapidly emerging waste stream in the world today. E-waste is also known as 'Waste Electrical and Electronic Equipments' or WEEE. As the term itself suggests, E-waste primarily refers to all the end-of-life equipments that utilize electricity for functioning. With growing urbanization and modernization processes, our dependence on electrical and electronic equipments is on a constant rise which, subsequently, results in a rapidly emerging market for these equipments. Once obsolete, these electrical and electronic equipments become E-waste or WEEE, one of the major global apprehensions in the present scenario. There are a number of reasons which calls for effective management and recycling of E-waste as an immediate intervention. For instance, a considerable portion of E-waste is disposed of in uncontrolled landfills in the developing world (mostly in middle and low-income countries) and informal E-waste recycling activities are practiced extensively (Ikhlaiel, 2018). The informal E-waste recycling sites are often the areas of uncontrolled pollution of several kinds – be it air, water, soil or noise pollution (Borthakur, 2014).

In the informal recycling sites, a number of hazardous practices are prevalent without any health and safety measures towards the workers and the environment. The treatment of waste printed circuit board (WPCB) in the informal E-waste recycling sites provides for a good case here. For leaching of precious metals from WPCB, cyanide (an exceedingly toxic chemical accountable for endangering human health and the environment) is largely used owing to its advantages in the form of low cost, extremely efficient recovery and simple operation (Lu and Xu, 2016). A number of studies have recognized the human health and environmental effects of E-waste recycling in developing countries. In countries like India and Southern part of China, high level of environmental emissions from persistent organic pollutants (POPs) and heavy metals are constantly being reported (Yoshida *et al.*, 2016).

Rapid technological advances and innovations make several older electronics out-of-date way before the end of their actual useful or functional life. As the lifetime of electrical and electronic equipments (EEEs) is becoming more and more shorter during the recent decades, E-waste recycling has become a major concern worldwide (Huang *et al.*, 2016). One excellent example in this context is the intensely progressing light-emitting diode (LED), liquid crystal displays (LCDs) panels and plasma display panels (PDPs) which replaced a considerable portion of cathode ray tube (CRT) sets in the recent times (Yao *et al.*, 2018). This is responsible for the generation of millions of waste CRT units. The study by Yao *et al.* (2018) further states that the data from the E-waste collection and pretreatment market specify approximately 50,000–150,000 million tons/year of waste CRTs presently collected in Europe alone, and this quantity is not anticipated to reduce in the near future. As argued by Janse *et al.* (2010: 495):

The consumer electronics (CE) industry has high turnovers and a rapidly growing demand. Electronic devices and gadgets are becoming “must-haves” for an ever growing number of consumers. CE is a fast clockspeed sector, i.e., new products are being introduced at a high rate [...] Accompanying the frequent introduction of new products is the rise of E-waste [...] To dump perfectly good products means throwing away value, which now WEEE gives the chance to manufacturers and importers to recover. This could be the clue to competitive edge in this highly competitive industry, with short lifecycles, steep price declines, and boiling pressure on profit margins.

The material composition of E-waste is diverse and thus, requires a comprehensive recycling effort. There are a range of valuable, critical and hazardous substances present in E-wastes which necessitates intense recycling towards avoiding health and environmental concerns in one hand and environmental problems accompanying the new materials in terms of their extraction and refining processes on the other hand (Cucchiella *et al.*, 2015). E-waste consists not only of toxic substances in the form of heavy metals such as lead, mercury, cadmium, but also generates added toxins, for example, Polybrominated dibenzo-p-dioxins and dibenzofurans (PBDD/Fs) and polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/Fs) during its informal management such as inappropriate acid leaching, open burning etc., in backyard or low-technology recycling initiatives (Zeng *et al.*, 2017a,b). Particularly in countries like India, China, Pakistan, the Philippines, Vietnam, Ghana, and Nigeria, acid extraction is widely practiced to retrieve precious metals such as platinum, gold, silver and palladium from Printed Circuit Boards (PCBs) and wires are charred in open spaces in order to recover copper and remove plastic (Ikhlaiel, 2018). Such E-waste recycling and dismantling activities are intentionally or unintentionally encouraged in developing countries including China, India or Pakistan owing to their quest for economic growth and craving for raw materials (Huang *et al.*, 2016). Further, the occurrence of heavy metals in E-waste is not only a cause of soil pollution, but also creates intense water pollution. For instance, heavy metals present in soil can find its way to the nearby waterbodies through rainfall and have the potential to also contaminate groundwater by means of leaching particularly under acidic conditions (Wu *et al.*, 2015).

Although wealthy countries do not exclusively generate the E-waste, these countries are responsible for substantially contributing to the E-waste apprehensions in the middle to low income countries owing to the regulatory uncertainties that permit export of EEEs for reuse, notwithstanding the actual product functionality (Heacock *et al.*, 2016). Most of the developed countries

have well-established all-inclusive E-waste management programmes, nevertheless, in the expense of the deviation of huge quantities of E-waste to the developing world towards appropriate disposal in their own countries (Li *et al.*, 2019). Even international legislations such as the Basel Convention of 1989 (which has been ratified by 181 countries) has been struggling hard to regulate the illegal export of E-waste from the developed to the developing countries (Orlins and Guan, 2016). As argued by Dias *et al.* (2019):

In the current ever-growing population (and ever-growing consumption per capita), improving resource efficiency is crucial. In addition to consumption reduction, other actions towards waste minimization such as reuse of products and recycling have an important role in contributing towards a sustainable resource management. For instance, in Australia, the recent creation of the regulatory framework and the national recycling scheme (NTRCS) have been able to divert significant amounts of E-waste from landfill. However, due to the lack of a downstream recycling industry and the shortfall of a mechanism to promote downstream recycling, the majority of the E-waste collected through the scheme is exported for processing overseas.

Similar to Australia, several other wealthy countries such as the USA, Canada and the European Union member states divert large volumes of E-waste to the developing countries. The imported E-waste feeds the informal recycling sites in the developing world (Borthakur, 2015). Considering the ever-increasing volume of E-waste in both the global north and global south, the toxic trade of it, the possible human health/environmental repercussions and the potential of extracting valuables from the waste, it is becoming increasingly essential to ensure its appropriate management practices and recycling is a core starting point here. Accordingly, in this chapter, we attempt to analyse the recycling of E-waste in terms of its significances and possible challenges. Environmental, human health and economic reasons for E-waste recycling has been evaluated. The processes of extraction of precious, valuable and rare earth metals from E-waste have been tabulated in details. The purpose is to provide the readers a comprehensive overview of the current E-waste recycling scenario and the future perspectives towards tackling this toxic category of waste in both resource and environment friendly ways.

Significance of E-Waste Recycling

Environmental and Human Health Reasons

The current management system of E-waste, especially in the developing countries, has enormous environmental and human health repercussions (Borthakur, 2016). It is well documented that in spite of the gradual progress of the legal recycling systems in the developing world, informal recycling facilities are still largely responsible for collecting and recycling of E-waste (Yoshida *et al.*, 2016). The rudimentary recycling and disposal practices can result in high occupational and incidental exposure to a range of hazardous substances, and generate locally severe environmental contamination (Labunska *et al.*, 2015). For instance, the heavy metals present in E-waste calls for special attention among the various toxic substances omnipresent in this toxic waste category owing to their non-biodegradability, mobility and toxicity (Wu *et al.*, 2015). As argued by Zeng *et al.* (2016):

The countries most affected by informal e-recycling are China (Guiyu and Taizhou), India (Bengaluru and Delhi) and some African countries (Lagos in Nigeria, Accra in Ghana), where E-waste has been recycled or disposed with little or no regulation, using less advanced technology. Heavy metals cannot be degraded into less hazardous end products, which is different from organic pollutants with biodegradable capability. Heavy metals derived from electronic waste (E-waste), such as, lead (Pb), cadmium (Cd), chromium (Cr), manganese (Mn), nickel (Ni), mercury (Hg), arsenic (As), copper (Cu), zinc (Zn), aluminum (Al) and cobalt (Co), differ in their chemical composition, reaction properties, distribution, metabolism, excretion and biological transmission.

The persistent organic pollutants (POP) present in E-waste are of no less concern. The regularly occurring POP in electrical and electronic equipments primarily consists of: polybrominated diphenyls, brominated flame retardants (polybrominated diphenyl ethers), polychlorinated biphenyls, dibrominated diphenyl ethers, polybrominated or polychlorinated dioxins and dibenzofurans dioxins, perfluoroalkyls and hexabromocyclododecanes (Grant *et al.*, 2013). All these toxins are of immense concern from the human health and environmental protection's perspectives. For instance, polycyclic aromatic hydrocarbons (PAHs) in the form of brominated flame retardants (BFR) and polychlorinated biphenyls (PCB) have the potential to accumulate in both soils and sediments and thus become obtainable for the uptake of both aquatic and terrestrial organisms when released into the environment adjacent to an E-waste handling facility (Labunska *et al.*, 2015). As put forth by Man *et al.* (2013):

Polycyclic aromatic hydrocarbons (PAHs) are usually produced via the incomplete combustion of organic substances and comprised of a diverse group of organic compounds [...] Polycyclic aromatic hydrocarbons in the environment have drawn much attention due to their toxicity and potential carcinogenic effects on humans. Soil serves as an enormous sink for the accumulation of organic contaminants and may allow the entry of PAHs into food chains. A number of studies have focused on the variation of PAH concentrations in different soil types. In general, it has been found that PAH concentrations in soil increase with the degree of anthropogenic impact, in both industrial and domestic land use.

Luo *et al.* (2015) argue that during various E-waste recycling efforts such as the burning of E-waste, a diverse range of toxic contaminants (including PAHs) are released into the immediate environment exposing the residents (residing in the vicinity of E-waste recycling facilities) and unprotected E-waste workers to these hazardous pollutants. For instance, polychlorinated dibenzofurans, polychlorinated dibenzodioxins and dioxin-like polychlorinated biphenyls are typically the POPs which are

Table 1 Toxic substances in E-waste and their health impacts

released during dismantling, incineration and smelting operations (Grant *et al.*, 2013). These contaminants have the potential to pass in to the food chain resulting in extended and unescapable exposure to people who resides in the neighborhood of an E-waste recycling area (Labunska *et al.*, 2015) (Table 1).

Economic Incentives

The limited quantity of matter, especially metals, on earth despite the population increase and yearning of humans to trail western consumption patterns will inescapably result in scarce primary resources and plentiful of urban wastes, calling for the harvest of compounds from anthropogenic waste (Billard, 2019). E-waste is known as a resource worldwide on account of the potential towards recovery of valued materials such as copper, iron, silver, gold, aluminum and several rare earth metals (Heacock *et al.*, 2016). Retrieval and recycling of these valuable metals from E-waste has, to a certain extent, the potential to lessen the overall global demand for new metal production and aid in decreasing the quantity of materials discarded in the landfills (Kumar *et al.*, 2017). For instance, the alteration of E-waste into a valued nanomaterial is considered as a sustainable and effectual method towards ensuring a circular economy (Liou and Jheng, 2018). Nevertheless, electronic and electrical equipments are usually not designed either towards their safe disposal or effectual recovery of the valuable materials (Heacock *et al.*, 2016). A number of conventional methods are regularly used to treat E-waste which comprises of repair, reuse and the reduced discarding of the residues by landfilling and incineration (Liou and Jheng, 2018). There already exist potentially wealthy reserves of secondary materials through major possession of EEEs in the industrialized nations (Pierron *et al.*, 2017). There are systematic methods in place in these countries which have the potential to ensure maximum resources recovery. Most of the E-waste in the developing world, on the other hand, is presently collected by individual collectors and recycled either by individuals or in small scaled facilities (Yoshida *et al.*, 2016).

Recycling of metals present in electrical and electronic equipments has the potential to decrease the necessity for mining of virgin materials (Heacock *et al.*, 2016). Here comes the concept of urban mining (UM) which could immensely contribute to the economy of the world today. Urban mines can acquire metals from waste products and thus, considered as an ideal alternative towards gathering raw metals which are else restricted in availability (Jo *et al.*, 2018). As Pierron *et al.* (2017) argue, “Urban mining

Table 2 Recovery of metals from E-waste

Source/type	Metal recovery/leaching	Processes	Recovery	Reference
Light-emitting diodes	Rare metals (Ga, In)	Combination of pyrolysis, physical disaggregation methods and vacuum metallurgy separation	Recovery efficiencies of 93.48% and 95.67%	Zhan <i>et al.</i> (2015)
Soil contaminated by E-waste	PBDES/Pb/Cd-contaminated electronic equipments	Elevated temperature (50 degrees c) in combination with ultrasonication (40 khz, 20 min) at 5.0 ml l ⁻¹ sunflower oil and 2.5 g l ⁻¹ carboxymethyl chitosan	Pb, and Cd were approximately 94.1, 93.4, 94.3, 99.1, 89.3, and 92.7 %	Ye <i>et al.</i> (2015)
Waste printed circuit boards (wpcbs)	Copper, nickel and iron	Cupric chloride solutions (hcl-cucl ₂ -nacl	98%) for copper, nickel and iron	Yazici and Deveci (2015)
Chloride solution of E-waste	Cadmium	Cyanex 923 impregnated amber lite xad-7hp resin	–	van Nguyen <i>et al.</i> (2015)
Gan based power device and led	Gallium	Acidic leaching	–	Swain <i>et al.</i> (2015)
ICT	Copper	Ammonia-based solution	90%	Sun <i>et al.</i> (2015)
Computer printed circuit boards	Cu-Zn-Ni	Bleaching process using ferric sulphate generated by leptospirillum ferriphilum dominated consortium	94.08% Cu, 99.80% Zn and 97.99% Ni extraction.	Shah <i>et al.</i> (2015)
Waste LCDs	Indium (in)	Sing various solid:liquid (s/l) ratios and solvents (acid mixtures)	60%	Savvilitidou <i>et al.</i> (2015)
Low-grade electric and electronic wastes	Copper	Eached in ammonia–ammonium sulphate solution	90%	Rudnik <i>et al.</i> (2015)
Coarsely ground printed circuit boards	Copper	Thermophilic bacteria using rotating-drum reactor	85%	Rodrigues <i>et al.</i> (2015)
Waste printed circuit boards	Copper	Bioleaching by acidithiobacillus ferrooxidans strain z1	81.43%	Nie <i>et al.</i> (2015)
Li-ion batteries	Mn(ii), co(ii), ni(ii) and li(i)	20% acorga m5640 in kerosene with agitation for 5 min at 30 °c a	91.2% Mn(ii), 89.3% Co(ii) and 95.6% Ni (ii)	Nayl <i>et al.</i> (2015)
Electronic scrap materials (esm)	Gold	Bioleaching	30%	Natarajan and Ting (2015)
Waste printed circuit board	In, lead, zinc and aluminum	Acid leaching–electrowinning process	98.66% for cu, 91.08% for sn, 91.25% for zn, 78.78%	Guo <i>et al.</i> (2015)
Circuit boards	Copper	Supercritical carbon dioxide	90% of the cu	Calgaro <i>et al.</i> (2015)
Discarded mobile phone	U and Ni	Acidithiobacillus ferrooxidans. Bioleaching	100% extraction of cu and ni	Arshadi and Mousavi (2015)
Cigs photovoltaic cells	Indium	Acid-resistant nanofiltration with liquid-liquid extraction	95%	Zimmermann <i>et al.</i> (2014)
Printed circuit boards	Palladium	Novel non-acid process	99.5%	Zhang and Zhang (2014)
Waste printed circuit boards (WPCBS)	Copper and other metals (i.e., Ni, Ag and Pd)	Acidic ferric sulphate solutions	(≥99% Ag/Pd)	Yazici and Deveci (2014)
Waste printed circuit boards		Acidithiobacillus ferrooxidans	Cu (96.8%), Zn (83.8%), and al (75.4%)	Yang <i>et al.</i> (2014)
Brass from waste electrical and electronic equipment	Copper and zinc	Leaching by sodium persulfate solution	–	Popescu <i>et al.</i> (2014)
Printed circuit boards	Zinc, copper, lead, nickel, cadmium and chromium	Bioleaching	48% for Zn, 93%. Cd, 48.5% and 53% for copper and nickel	Karwowska <i>et al.</i> (2014)
Recycling industry electronic waste	Cu, Zn, Ni, Cd, Al, Cr, Pb	Bioleaching by consortium of sulfobacillus thermosulfidooxidans and thermoplasma acidophilum	–	Ilyas <i>et al.</i> (2014)
Electronic waste material	Copper	Bioleaching mesophilic acidithiobacillus thiooxidans.	(60%)	Hong and Valix (2014)
Spent lithium-ion batteries	Li, mn, co, and ni	Hydrometallurgical extraction of metals	90%	Vieceli <i>et al.</i> (2018)
E-waste	Copper, iron and lead	Using citrate solutions	90%	Torres <i>et al.</i> (2018)

Table 2 Continued

Source/type	Metal recovery/leaching	Processes	Recovery	Reference
Co-fired ceramic an E-waste	Silver	Wet chemical reduction	–	Swain <i>et al.</i> (2018)
Electric and electronic equipment	Ga, Ge, In and Sn	Secondary copper smelting	–	Avarmaa <i>et al.</i> (2018)
Lcd	Indium	Non-crushing leaching method	96.80%	Zhang <i>et al.</i> (2017)
Printed circuit boards (pcbs)	Pb, Sn, Zn, Cu, Al	Bioleaching	85.23% Zn, 76.59% Cu and 70.16% Al	Xia <i>et al.</i> (2017)
Electronic waste	Gold	Moderate thermophiles	90%	Wu <i>et al.</i> (2017)
		Hydrometallurgical leaching solution through spontaneous reduction by polyaniline		
Aluminum electrolytic capacitors	Aluminum and Iron	Involving heating treatment, crushing, sieving, and magnetic separating	96.52% and 98.68% of aluminum and iron	Wang and Xu (2017)

Source: Prepared by the authors (2019).

is a construct of anthropogenic resources between landfill mining and recycling to integrate secondary material flows and stocks into the Circular Economy". The term primarily represents the methodical recycling and reuse of anthropogenic resources especially from the urban areas and thus, contains all variants of anthropogenic stocks in the form of buildings, landfills, infrastructure, emissions, products and industries (Avarmaa *et al.*, 2019). It is responsible for recovering the metal components from products that are generally thrown away as a part of people's everyday lives and subsequently refined these components into raw materials (Jo *et al.*, 2018). Owing to its utility prospects, urban mining is developing as a significant substitute towards collecting natural resources (Jo *et al.*, 2018). As put forth by Zhang *et al.*, (2019: 210):

Urban Mining (UM) concerns all the activities and processes of reclaiming compounds, energy and elements from products, buildings and waste generated from urban catabolism" [...] Among various categories of urban mines, personal electronics represent a typical, high-tech consumer device having a short lifecycle (usually less than 5 years) and containing substantial contents of valuable materials. Unused personal electronics are inclined to become idle or be discarded carelessly because of their relatively small size, making them constitute an important category of urban mines in recent years.

It is widely accepted that E-waste possibly releases polyhalogenated organic compounds and toxic metals, its landfilling and incineration methods cause environmental contamination and health menaces and thus, a feasible longstanding resolution is the exploitation of resources retrieved from this category of waste to initiate a circular economy (Liou and Jheng, 2018). Accordingly, urban mining has risen as an essential concept amongst industrialists, environmentalists, businesses and politicians (Avarmaa *et al.*, 2019). The waste printed circuit boards (WPCBs) found in all electrical and electronic equipments, which are responsible for providing the interconnection between hardware and software, are a good example here. Due to the presence of the precious metals, it is considered as the utmost valued components in E-waste (Lu and Xu, 2016). As argued by Tuncuk *et al.* (2012):

[The] WPCBs, which are resource-rich, are generally referred to as "urban mines". To illustrate, printed circuit board (PCB) of a PC can contain up to 20% Cu and 250 g/ton Au, which are significantly high i.e., 25–250-fold for gold and 20–40-fold for copper when compared with gold ores (~1–10 g/ton Au) and copper ores (~0.5%–1% Cu), respectively. Recycling turns WEEE into a secondary resource allowing the recovery and reuse of metals and non-metals contained and mitigating the environmental impact of WEEE.

Although the techniques for the recovery of the base metals from WPCBs are considered as mature, retrieval of precious metals from the same is still inappropriate in practice (Lu and Xu, 2016). As further put forth by Lu and Xu (2016), currently, the WPCBs with high concentration of expensive metals such as gold, silver, platinum, palladium etc., are the key target objects and thus, are recycled through unregulated and crude methods such as open acid washing triggering grave human health damage and environment contamination. Accordingly, it is essential to ensure recovery methods for precious and valuable metals with least repercussion to the environmental and human health. Further, it is also essential to understand consumers' E-waste disposal behavior in terms of their socio-cultural, environmental and economic considerations in order to ensure maximum E-waste recycling towards extraction of majority of the valuable and precious metal components (Borthakur and Govind, 2017).

Recovery of Metal Components From E-Waste

We have already discussed in the previous sections the significance of recovery of metals in the form of precious, valuable and rare earth metals from E-waste. There are a number of studies carried out by diverse research groups across the globe to address the recovery processes to ensure optimum response. Table 2 summarizes some of these processes and their recovery potential of metals from E-waste.

Conclusions

With growing urbanization and modernization processes, our dependence on electrical and electronic equipments is on a constant increase giving rise to a rapidly emerging market for these equipments. As these equipments become obsolete, they contribute to one of the most hazardous waste streams in the world i.e., E-waste. There are a number of reasons which calls for effective management and recycling of E-waste as an immediate intervention. For instance, the material composition of E-waste is diverse (consisting of precious, rare earth and valuable metals along with heavy metals and POPs) and thus, requires a comprehensive recycling effort. In the informal E-waste recycling sites, a number of hazardous practices are prevalent without any health and safety measures towards the workers and the environment. Thus, the current management system of E-waste, especially in the developing countries, has enormous environmental and human health repercussions. The heavy metals and POPs present in E-waste especially aggravate the environmental and human health concerns. There are further concerns about the rapid technological advances and innovations make several older electronics out-of-date way before the end of their actual useful or functional life. This is responsible for generating more and more quantity of E-waste with every passing year.

Recycling of E-waste is able to attain considerable attention during the last decade. As mentioned in the previous sections, one primary reason for this being the fact that, the quantity of E-waste generated is increasing all over the globe, while E-waste management practices are still at a very primitive stage. For instance, in most of the developing countries, the recycling efforts are still dominated by the informal sector with intense environmental and human health repercussions. Developing countries are in a better position in terms of E-waste recycling, however, they are always accused of encouraging the illegal trade of E-waste to the global south. Nevertheless, there are a number of E-waste recycling enterprises which are able to work towards responsible and sustainable disposal practices. These organizations have channelized their work efforts towards different directions and participate in different capacities towards E-waste recycling. They may participate in E-waste recycling as a non-profit organization or as a producer responsibility organization or have certain other roles. Recupel, Belgium, for instance, is a non-profit association responsible for 'organizing the collection and processing' of discarded electronic appliances and light bulbs. There are a number of such efforts in the developed world.

The processes of recovery of valuable metals from E-waste have also found significant attention in the recent past. We have tabulated a few of these efforts in our chapter. These processes are essential to ensure the maximum extraction of precious/valuable/rare earth metals from E-waste, popularly known as 'urban mines'. Nevertheless, we argue that as a waste category which gained attention only in the recent decade, it is essential to continue studying the E-waste streams across the globe and formulate policy responses to address this stream of waste accordingly.

Introduction

Due to their high stiffness, strength, and ease of shaping, fiber reinforced polymers (FRPs) are attractive alternatives to steel and several nonferrous metals for a wide range of applications, including automobiles, shipbuilding, circuit boards, construction materials, and household equipment. However, due to the increasing severity of global environmental issues, such as climate change and fossil fuel depletion, several drawbacks of conventional FRPs are apparent because glass fiber, the major enhancement material, is produced through the material mixture input and causes intense energy demand.

To solve the sustainability challenges of the conventional glass fiber, a natural way is to shift to renewable sources for fiber production. For this purpose, plant fibers have been extensively investigated as a renewable alternative to traditional glass fiber reinforcement. Plant fibers also help circumvent the problem of glass fiber incineration. Plant fibers are combustible, and the released energy from combustion can be recovered. For application in the transport sector, the lower density of plant fibers ($\sim 1.5 \text{ g cm}^{-3}$) compared with glass fibers ($\sim 2.5 \text{ g cm}^{-3}$) is attractive: Plant fibers allow to produce lightweight structures and subsequently incur less fuel consumption in vehicle use. Thus plant fibers (such as flax, hemp, and jute fibers) are considered to be a feasible replacement for glass fibers. Currently, Plant Fiber Reinforced Polymers (PFRPs) only encompass $\sim 1.9\%$ of the total FRP market, compared with an 87% share for Glass Fiber Reinforced Polymers (GFRPs) (Shah, 2013). However, the market for PFRPs is strongly expected to grow. It is forecasted that by 2020, plant fibers together with other type of fibers derived from biobased sources will represent up to 28% of the total market of reinforcement materials (Yan *et al.*, 2014). PFRPs have already gained universal acceptance in the production of interior parts for the automotive industry (Koronis *et al.*, 2013). In fact, 95% of the commercial applications of PFRPs are currently for components in secondary/tertiary structures in the automotive industry, for example, interior components such as door panels (Shah, 2013). Therefore, PFRPs are expected to sustain some degree of loading or provide functional properties similar to those of components manufactured using traditional composites, for example, GFRP. Flax fibers are the most widely used plant fiber for composite reinforcement due to its exceptional mechanical properties (Shah, 2013). With wide availability, low cost, low density, highly specific properties, and eco-friendly image, flax fibers have been portrayed as prospective substitutes for the traditional composite reinforcements, specifically E-glass (Yan *et al.*, 2014).

To compare flax FRPs with GFRPs, the life cycle assessment (LCA) method can be applied to provide a detailed analysis in terms of environmental impacts. Current LCA studies on flax FRP are generally based on case studies with a predefined structure, and the designs of the flax FRPs are configured based on certain criteria to maintain a similar functionality with the GFRPs. For example, Boland *et al.* (2016) applied the same geometry criterion to compare the life cycle environmental impacts of various short natural fiber injection molded composites and the GFRPs for automotive component. On the other hand, the equal stiffness criterion is applied by multiple studies for the flax FRP and the reference GFRP comparison (Rajendran *et al.*, 2012; La Rosa *et al.*, 2013; Deng and Tian, 2015). Most of these studies confirmed the environmental benefits of using the flax FRP compared with the GFRP in terms of the GHG emissions and fossil depletion. However, the studies are constructed based on specific situations. The composition and mass of the flax FRPs are predefined. These case-oriented LCA results may not be able to provide guidance in the design stage since different situations require different composite structures. In this sense, a flexible LCA method is needed incorporating a material model predicting the corresponding mechanical parameters, based on which an optimized structure of the flax FRPs can be envisaged to guide subsequent product development and the environmental impact can be assessed with a specific design principle.

In this study, a parametric cradle-to-grave LCA model will be developed to assess the environmental impact of flax FRPs with different design specifications for automotive applications. Furthermore, the environmental impacts of two commonly applied flax FRPs (compression molded flax mat reinforced polymer composite and injection molded short flax fiber compound composite) are assessed and compared with conventional GFRPs.

Mechanical Properties of Flax Fiber Reinforced Polymers

Based on an extensive literature survey (Arbelaz *et al.*, 2005; Bodros *et al.*, 2007a,b; Bos *et al.*, 2006; Erasmus and Anandjiwala, 2009; Goutianos *et al.*, 2006; Li and Sain, 2003; Nystrom *et al.*, 2007; Van den Oever *et al.*, 2000; Yu *et al.*, 2009), the mechanical properties (tensile modulus and tensile strength) of different flax FRPs are summarized in Fig. 1. Applying Ashby plot (Ashby, 2005), the flax FRPs are categorized based on reinforcement formats (nonwoven mat, compound, unidirectional alignment, and woven fabric) and matrix type (thermoplastic and thermoset) focusing on conventional polymer matrices. The six

Fig. 1 Typical tensile properties for categorized flax fiber reinforced polymers.

subgroups presented in **Fig. 1** resemble an Ashby plot. The placement of these subgroups on the plot present increasing tensile properties in the following order: Injection molded composites (3D-random), nonwoven mat reinforced composites (2D-random) either via compression molding or Resin Transformation Moulding (RTM), woven fabric reinforced composites, and unidirectional fiber reinforced composites (by compression, RTM, or prepregging). The tensile strength and modulus tend to be linearly related with each other. Observing the variation in properties between the different distinguished categories, it can be concluded that the thermoset-based flax FRPs show better mechanical properties than the thermoplastic-based flax FRPs. Furthermore, the manufacturing techniques also have a noticeable effect on the composite mechanical properties, as demonstrated by the unidirectional flax FRPs when comparing the tensile properties between the hand lay-up and compression molding, RTM, or prepregging methods.

Besides several conventional polymers, for example, Polypropylene (PP), epoxy, polyester, etc., a further step, to use a biobased polymer matrix, is investigated as well (Zini and Scandola, 2011; La Mantia and Morreale, 2011; Koronis *et al.*, 2013). Typically applied biobased polymers include Polylactic Acid and Polyhydroxyalkanoates (Mukherjee and Kao, 2011; Le Duigou *et al.*, 2008; Chen *et al.*, 2011; Bodros *et al.*, 2007a,b; Roussiere *et al.*, 2012; Wrobel-Kwiatkowska *et al.*, 2007; Miller *et al.*, 2013). Other biobased polymers, for example, protein derived polymer (soy protein and wheat gluten) have also been analyzed (Lodha and Netravali, 2005; Huang and Netravali, 2007; Chabba and Netravali, 2004; Wretfors *et al.*, 2009; Hemsri *et al.*, 2012; Reddy and Yang, 2011). Comparison of the mechanical properties of flax FRPs with conventional matrix and biobased matrix reveals that, although a biobased matrix does not allow to reach the same maximum product properties as can be achieved in the case of unidirectional composite with conventional polymer matrix, both matrix types bring on comparable tensile moduli and strength values in the lower and medium levels (**Fig. 2**). Another particular phenomenon for biobased polymer matrices is that the tensile modulus and strength are not linearly related with each other. Products with low modulus and with relatively high strength are reported, as reflected in the unidirectional composites with soy protein matrix (Lodha and Netravali, 2005; Huang and Netravali, 2007). This indicates that large failure strains are present.

Mechanical Properties Modeling

To simulate the mechanical properties (tensile modulus and strength) of PFRPs, a modified generalized rule-of-mixture (ROM) model has been applied to derive the modulus and strength (Shah, 2013):

$$E_c = (\nu_f \eta_{IE} \eta_o \eta_d k E_f + \nu_m E_m) (1 - \nu_p)^2 \quad (1)$$

$$\sigma_c = (\nu_f \eta_{IS} (f \eta_o) k \sigma_f + \nu_m \sigma_m^*) (1 - \nu_p)^2 \quad (2)$$

where E_f and σ_f are the fiber modulus and fiber strength; ν_f and ν_m are the fiber and matrix volume fractions; η_{IE} and η_{IS} are the reinforcement length efficiency factors for modulus and strength modeling, respectively; η_o is the reinforcement orientation distribution factor while f accounts for the composite bear-loading efficiency to reconcile the theoretical values with the

Fig. 2 Tensile properties of flax fiber reinforced polymers with biobased and conventional polymeric matrix.

experimental values in strength calculation; E_m and σ_m^* are the matrix modulus and matrix tensile stress at the fiber failure strain, respectively; the $(1-\nu_p)^2$ factor incorporates the negative influence of porosity on the tensile properties of the PFRPs; η_d incorporates a fiber diameter distribution factor reflecting the fact that the tensile modulus of PFRPs decreases quasi-linearly upon an increase in fiber diameter; and the fiber area correction factor k addresses the impact of the simplified assumption of a circular cross-sectional shape, which tends to overestimate the true cross-sectional area.

η_{IE} can be calculated according to Cox's shear lag theory (Cox, 1952) using the parameters of fiber length (l_f), fiber diameter (d_f), and for a square-packing arrangement. η_{IS} incorporates the interfacial strength of the flax fibers into the matrix and is determined by the Kelly and Tyson (1965). Both factors have a range from 0 to 1. The values of η_{IE} and η_{IS} are largely determined by l_f/l_d and l_f/l_c , respectively, where l_c is the fiber critical length defined in the Kelly–Tyson model. When the fiber length is low (<0.5 mm), both η_{IE} and η_{IS} are very sensitive to l_f . Under typical conditions, η_{IE} and η_{IS} quickly reach 0.8 when l_f increases from 0 to 0.5 mm (Shah, 2013). An enhancement in the fiber/matrix interfacial shear strength has a noticeable effect on η_{IS} when l_f is below 3 mm. It is worth noting that when the fiber length surpasses 6 mm, η_{IE} and η_{IS} both approach the unit value. Typical obtained fiber lengths are summarized according to reinforcement formats (Faruk et al., 2012; Shah, 2013). Typical values for η_{IE} and η_{IS} are collected for the compound (Bos et al., 2002; Shah, 2013) and mat structures (Bos, 2004; Shah, 2013). For reinforcement formats of woven fabric and unidirectional alignment, the long fiber length should induce unit values of η_{IE} and η_{IS} .

η_o , the orientation distribution factor, can be estimated from the Krenchel orientation distribution factor. η_o ranges between 0 (all fibers aligned transverse to the stress direction) and 1 (all fibers aligned parallel to the stress direction). The values of η_o for 3D or 2D randomly distributed fibers, as in the cases of compound and nonwoven mats, are 0.2 and 0.375, respectively. The η_o value for the woven fabric reinforcement format relies on the ply orientation, which ranges from 0.25 ($[\pm 45^\circ]$) to 0.5 ($[0^\circ, 90^\circ]$). Finally, the unidirectional fiber format should present the unit value of the orientation factor if an acceptable alignment is achieved. The bearing-load efficiency factor, f , is applied to η_o due to the fact that a large discrepancy can be observed between theoretical results from the Kelly–Tyson model and measured values in strength calculation (Garkhail et al., 2000). This factor is usually fitted from the experimental results (Garkhail et al., 2000; Bos, 2004). Based on the data for flax FRPs in (Bos, 2004; Bos et al., 2006), f is derived to be 0.22–0.42 for 2D randomly distributed flax fibers and 0.53–0.63 for 3D randomly distribution flax fibers. The fiber diameter distribution factor, η_d , has recently been proposed in (Summerscales et al., 2011), and it ranges between 0 and 1. The η_d value was determined for jute fiber, 0.46, through fiber structure analysis. In estimating the fiber area correction factor k ($k=1$ for a circular fiber cross-section), researchers show that a 2.55 correction factor is applicable to flax fiber (Thomason et al., 2011), compared with 1.42–2.08 for jute fiber and 1.99 for sisal fiber (Virk et al., 2012; d'Almeida et al., 2012).

The porosity content (ν_p) in a composite has a detrimental effect on its mechanical properties. Typically, a 5% limit is placed on a composite serving structural functions, for example, a composite used in automotive or marine applications. For PFRPs below 40 vol% fiber content, such a void limit can be satisfied. However, the porosity content can sharply increase to 25% if the fiber volume fraction exceeds 40%.

Table 1 Parameters of flax FRPs in automotive application

Reinforcement	Manufacturing	Structure	Load bearing
Flax mat	Compression molding	Panel	Bending
Short flax fiber	Injection molding	Strut	Tension

Abbreviation: FRPs: Fiber reinforced polymers.

Table 2 Material mass indices for common structures of plates and tensile bars under different loading types

Flax structure	Constraint	Variable	Objective	Load	Mass index
Short flax-PP	Length	Cross-section area	Equal stiffness	Tension	ρ_c / E_c
Short flax-PP	Length	Cross-section area	Equal strength	Tension	ρ_c / σ_c
Flax mat-PP	Length, width	Thickness	Equal stiffness	Bending	$\rho_c / E_c^{1/3}$
Flax mat-PP	Length, width	Thickness	Equal strength	Bending	$\rho_c / \sigma_c^{1/2}$

Abbreviation: PP: polypropylene.

Life Cycle Environmental Impact of Flax Fiber Reinforced Polymers

Goal and Scope

The goal of this LCA is to analyze the environmental impact of flax fiber production and cradle-to-grave environmental impact of flax FRPs compared with conventional GFRPs for automotive application, assuming a 200,000 km driving distance during the functional life span, which represents an average automotive lifespan in Europe. The flax FRPs are assumed to be used in European automotive industry since it is the strongest promoter for the application of plant FRPs. The two types of flax FRPs (**Table 1**) are widely used to produce automotive components replacing traditional GFRPs (Holbery and Houston, 2006): Injection molded short flax fiber reinforced polypropylene compound (short flax-PP), and compression molded flax mat polypropylene film (flax mat-PP) are covered in the detailed analysis. Both composite structures are included in the study to substitute glass mat-PP and short glass fiber-PP. For the glass mat-PP, a 9-kg conventional glass fiber mat reinforced with polypropylene panel (20% v/v) for the inner part of the car hatch for the Mercedes-Benz A-class (Jambor and Beyer, 1997). In the case of short glass fiber-PP, a hypothetical injection molded short glass fiber reinforced polypropylene with the same 9 kg mass is considered for comparison. Incineration with energy recovery is chosen to be end-of-life (EoL) scenario for both composites.

Design of the flax fiber reinforced polymers

To implement a systematic comparison, designs of flax FRP and GFRP must be constructed on a functional equivalence basis. Many factors, for example, physical properties, geometry, and cost, are involved in component design as the main design criteria. For composites applied in structural applications, two widely used criteria for equivalent performance are equal stiffness and strength. The material indices outlined in Ashby (2005) can be used to characterize the equivalent design under the designated objective and constraint (**Table 2**). E_c and σ_c in **Table 2** stand for tensile modulus and strength respectively, and ρ_c is composite density. Therefore, these material indices contain only the intrinsic material properties and are proportional to the mass of the panel/strut structure.

To determine the functional equivalent mass of the flax FRP, the mass index (MI_{GFRP}) of the targeted and mass (m_{GFRP}) of the GFRP are used as baseline values. Then, the mass of flax FRP is calculated according to its mass index ($MI_{\text{flax FRP}}$):

$$m_{\text{flax FRP}} = \frac{MI_{\text{flax FRP}}}{MI_{\text{GFRP}}} m_{\text{GFRP}} \quad (3)$$

The required mechanical properties can be calculated according to the generalized ROM with Eqs. (1) and (2) for modulus and strength calculation, respectively. It should be noted that for the panel structures subject to bending, the Ashby method strictly requires the flexural modulus and strength, that is, the modulus/strength measured under flexural loading, in addition to the tensile modulus/strength. Compared with the elastic modulus measured by means of a tensile test, flexural loading induces shear strains within the composite structure. Since the shear modulus value is lower than the elastic modulus ($\text{shear modulus} = \frac{\text{elastic modulus}}{1 + \text{poisson ratio}}$), the obtained strain would then be inflated leading to a reduction in the measured flexural modulus. Because no pragmatic theoretical model on flexural modulus/strength can be found, the tensile modulus is used as a proxy for the flexural properties in this analysis. This simplification was also applied in Rajendran et al. (2012) for a functionally equivalent design of a panel structure. Rodríguez et al. (2005) measured the flexural modulus and tensile modulus for various natural FRP composites. Their results show that the deviations between the respective flexural moduli and tensile moduli are within 10%.

Fig. 3 Unit processes applied during the life cycle of flax fiber and glass fiber reinforced composites.

In this analysis, the functional unit of the comparison is set to use flax mat-PP or short flax fiber-PP replacing the corresponding GFRPs under equal stiffness and strength criteria. To construct formulations of flax FRP and GFRP for comparison, the 9 kg glass mat-PP and short glass fiber-PP with 20% v/v are used as baseline values. Eq. (1) is applied to calculate the E_c , which is needed to derive the mass index. Then, the corresponding mass of flax mat-PP can be determined by Eq. (3). With the references of the glass mat-PP and short glass fiber-PP composites, the masses of flax FRPs under the corresponding criteria are calculated according to Eqs. (1)–(3).

System description

Fig. 3 Depicts the system boundary for this LCA study. The geographical boundary for the LCA study is assumed to be a European setting. Specifically, France is the dominant flax fiber producer, and thus this location is selected for flax collation and fiber processing. In France, after harvesting, the green flax straw is exclusively dew-retted to decompose the pectin binder and thus facilitate the subsequent fiber extraction processes. The retted flax straw is crushed by a pair of fluted rollers and beaten by a rotating blade that forces the internal woody tissue (shive) to fall off. Multiple products, for example, long flax fibers, short flax fibers (flax tows), shives, flakes, and seeds, are obtained after the extraction (scutching). Then, the scutched long fibers are refined by the hackling process to remove woody particles. Two products are generated from hackling: Hackled long fibers (slivers) and hackled tows.

The hackled long fibers, being the most valuable product, are used to produce mat for compression molding or compound for injection molding. Afterwards, these will be used to replace the correspondent GFRP in the automotive applications. In automotive application, a change in mass typically induces a change in the fuel consumption rate. In addition to mass, durability (or service life) is another crucial factor determining the use phase. Due to lack of information on the service life of flax FRPs, initial treatment is to assume both flax FRPs and GFRPs can maintain the 200,000-km functional lifespan without need of replacement. Incineration with energy recovery is a valid scenario for composite disposal. In general, three common waste incineration technologies with energy recovery are available: Electricity as the only energy output, heat as the only energy recovery result, and coproduction of heat and electricity (CHP). CHP is the current mainstream technology and was selected during the LCA modeling of incineration as an EoL treatment scenario in this analysis.

Allocation

The upstream environmental effects may be partitioned based on the relative masses or prices when multiproducts are generated in unit processes. To account for the fact that flax hackled long fibers are the main incentive for farmers to cultivate flax, economic allocation is applied to estimate the environmental impact. The yield and yield data are sourced from literature (Le Duigou *et al.*, 2012).

Life Cycle Inventory

Fiber cultivation, processing, and composite fabrication

The inventory data for flax cultivation, fiber production, and composite fabrication have been documented in details in literature (Deng *et al.*, 2016; Duflou *et al.*, 2014). The flax cultivation and fiber extraction in France is modeled since France is the dominant producer of flax fiber (Deng *et al.*, 2016). For glass fiber, the Life Cycle Inventory (LCI) in the Ecoinvent database 2.2 for “glass fiber, at plant/kg/RER” is the primary source (Kellenberger *et al.*, 2007). The LCI data of the PP granules and PP films production, which are used as input for the injection molding and compression molding processes respectively, have been documented in the Ecoinvent report (Hischier, 2007).

Composite use

The composite use phase contains two aspects: The fuel use related to the mass of the flax FRPs and replacement ratio ($\lambda = \frac{\text{GFRP lifetime}}{\text{Flax FRP lifetime}}$) of flax FRPs if flax FRPs have a different service life as the GFRPs.

Table 3 Fitted fuel consumption among different vehicles

Type	Driving cycle	Fuel economy	R ²
Cars	0–60 mph; tacc. = 9.2–9.8 s	$FC = 0.0035M + 3.9703$	0.4177
Light trucks	0–60 mph; tacc. = 9.5–10.1 s	$FC = 0.0037M + 5.2092$	0.6084
Gasoline cars	MVEG cycle	$FC = 0.00335M + 2.8492$	0.86
Heavy trucks	Not available	$FC = 0.0034M + 7.4452$	0.9841

Table 4 Inventory data for the incineration of flax/glass-based composites

Parameter	Unit	Applied value
Flax fiber	MJ kg ⁻¹	20
Glass fiber	MJ kg ⁻¹	−1.7
PP	MJ kg ⁻¹	48.7
Electricity	%	11.3
Heat	%	31.3

Abbreviation: PP: polypropylene.

For the first aspect, the fuel–mass correlation can be presented in the following equation (Kim and Wallington, 2013):

$$FC = FRC \times M + B \quad (4)$$

where FC is the fuel consumption or fuel economy (L/100 km); FRC denotes the fuel consumption reduction coefficient (FRC) [L/(100 km*kg)] determined by rolling, gradient, and acceleration resistance; M is the vehicle mass in kg; and B is a constant representing the parasitic loss (L/100 km). The literature survey indicates that FRC s for gasoline cars show limited variation across sources: From 0.0033 to 0.0037 L/(100 km*kg) (shown in Table 3). In the automotive application, an important distinction should be made in an LCA study: Vehicle LCA and component LCA. For the component LCA in this study, the allocation of fuel use to the specific vehicle component follows the method proposed by Kim and Wallington (2013):

$$FC_c = FRC \times M_c \quad (5)$$

where FC_c stands for the fuel consumption of the specific composite component and M_c is its mass. In this research, the applied FRC is 0.0033 L/(100 km*kg), a typical value for gasoline cars. Eq. (5) essentially assumes that the fuel consumption for a vehicle component should be its mass-induced fuel consumption. The parasitic loss, represented by the constant offset B in Eq. (4), is irrelevant in a vehicle component.

For the second aspect, determining the exact value of λ is not evident. The major factor limiting the durability of flax FRPs is their high moisture absorption caused by the hydrophilic nature of biobased materials. Moisture absorption leads to fiber swelling and subsequently causes dimensional instability and, more importantly, deterioration of the composite mechanical properties (Stamboulis et al., 2000). In real practice, flax fibers can be surface treated to reduce the moisture absorption (Lincoln et al., 2008). Thus, in the study, the replacement ratio, λ , is assumed to be the unit number from a practical perspective.

Incineration with energy recovery

The net heating values, or low heating values, documented in the Ecoinvent database, were adjusted to fit the specific values of the targeted composites (Table 4). The average net energy recovery efficiencies, 31.3% (in the range of 10.5%–66.8%) for thermal and 11.3% (in the range of 3.4%–23.7%) for electricity were applied based on the average values of 44 European waste incineration plants with combined heat and power generation (see Table 4). The recovered energy (electricity and heat) was modeled to substitute for primary electricity and heat generation in Europe. (Electricity, production mix UCTE/RER U (Frischknecht et al., 2007) and Heat, natural gas, at industrial furnace > 100 kW/RER U in the Ecoinvent dataset (Zah and Hirschier, 2007). The emissions were calculated according to the coefficient emission factors of the elements, which are documented in the Ecoinvent report (Doka, 2003). The detailed procedure to construct the inventory of flax FRP and GFRP during the EoL phase is documented in (Deng et al., 2016).

Impact assessment method

The ReCiPe midpoint (H) impact assessment method (Goedkoop et al., 2009) was used in the LCA study. The evaluation was performed using Simapro® version 7.2.4. Since the LCA study covers all the life cycle stages of flax FRPs, the biogenic carbon was treated as global warming neutral. The economic allocation principle has been applied for the environmental impact assessment.

Fig. 4 Masses of flax fiber reinforced polymer relative to GFRPs under different design criteria.

Results and Discussion

Life Cycle Environmental Impact Analysis of the Design Criteria for Flax Fiber Reinforced Polymers Selection

For automotive application, the environmental impact from the use phase is generally the most significant constituent. Thus, the functionally equivalent mass is regarded as an influential parameter for the life cycle impact assessment. Fig. 4 clearly indicates only the equal stiffness criterion can result in lower mass design compared with the 9 kg GFRP references. Within the range of 5%–65% v/v, flax mat-PP presents consistent mass reductions compared with the 20% v/v glass mat-PP reference while short flax fiber-PP starts to gain mass reduction from 20% v/v onwards. On the other hand, the equal strength criterion contributes to elevated masses compared with the reference short glass fiber-PP composite.

Based on the mass analysis, we further select the 20% v/v for flax FRP as the baseline scenario to quantify the life cycle impacts under different design criteria. As shown in Fig. 5(a), lower life cycle impacts can be observed in 14 out of 17 impact categories, typically 20%–50% reductions. In particular, a 13% decrease in the climate change category and a 14% reduction in fossil depletion are achieved. Moreover, for impact categories of ozone depletion and human toxicity, up to 70% reductions can be attained. Exceptions to this observation include the categories of ionizing radiation, marine eutrophication, freshwater ecotoxicity, and agricultural land occupation. The higher burden in ionizing radiation is due to the fact that flax cultivation and fiber extraction are highly concentrated in France where a significant fraction of the electricity generated is obtained from nuclear power plants. For other impact categories, the higher environmental impact of the flax mat-PP is found to be caused by the use of fertilizers and pesticides in flax cultivation.

Compared with the mat reinforced composites, environmental impacts of short flax fiber-PP composite present virtually the same environmental impacts in multiple impact categories compared with the short glass fiber-PP composite (Fig. 5(b)). This is explained by the fact that the short flax fiber-PP leads to a virtually equal mass (9.2 kg) structure in comparison to the 9 kg conventional short glass fiber-PP combination.

When the equal strength criterion is used, in both cases shown in Fig. 5, the relative environmental benefit observed for the equal stiffness analysis is largely reverted into a burden compared with GFRP. A significant inflation from the original levels obtained under equal stiffness conditions (approximately 40% increase for flax mat-PP and 25% increase for short flax fiber-PP) was observed. The large performance gap in strength between flax FRPs and GFRPs that explains this shift is also observed by other researchers (Bos, 2004).

Analysis of the Optimal Volume Fraction of the Flax FRPs

At the baseline level, the volume fraction of the flax FRPs is set to be the same as the GFRPs for comparison. In practice, this is not necessarily the case: A designer can increase or lower the volume fraction of flax due to different concerns, such as the available manufacturing equipment, the supply of qualified flax fiber, and the cost of the flax fiber. Thus, it is beneficial to evaluate the influences of different volume fractions on the life cycle impact of the flax FRPs. The change in fiber volume fraction has dual effects on the material indices. On the one hand, since the density of the flax fiber (1.5 g cm^{-3}) is higher than the PP matrix (0.96 g cm^{-3}), higher volume fraction will create higher composite density, and thus, lift up the material indices. On the other hand, more fiber

Fig. 5 Life cycle impact comparison between flax fiber reinforced polymers and GFRPs to equal stiffness and equal strength design criteria: (a) Flax mat-polypropylene (PP); (b) short flax-PP.

enhancement will improve the mechanical properties of the composite, and thus, lower the material indices. In this study, the accumulated impacts on the material indices are specifically calculated for short flax fiber-PP and flax mat-PP composites under equal stiffness criteria since it has been shown that flax FRPs are not proper candidates when strength is the main concern. The material indices of 20 vol% glass mat-PP and short glass fiber-PP composites are used as the references. The life cycle CO₂ emissions are presented in Fig. 6 due to the global concerns on global warming, and because reducing carbon emissions are the main incentive to replace glass fibers with flax fibers.

The results in Fig. 6 provide some insights on the design of the flax FRP. The first observation reveals that different types of composite exhibits different patterns when fiber volume increases. The steady decrease of the life cycle CO₂ emissions of

(a)

(b)

Fig. 6 Life cycle CO₂ emissions with changes in volume fraction: (a) Short flax fiber-polypropylene (PP); (b) flax mat-PP.

the short flax fiber-PP can be explained by the fact that the improved composite modulus (E) outpaced the increase in density (ρ_c), leading to increased material indices (ρ_c/E_c for short flax fiber-PP). Therefore, the mass of the short flax fiber-PP under the equal stiffness criterion will gradually become lower when volume fraction increases, and therefore lower the life cycle carbon emissions (Fig. 6(a)). However, the results of the flax mat-PP composite are much different. Minimal points of the life cycle CO₂ emissions present when the fiber volume fraction increases from 5% v/v to 65% v/v. Depending on the tensile modulus of the flax fiber, the optimal volume fractions of the fiber changes from 28% v/v to 32% v/v (Fig. 6(b)). Such a different pattern can be explained from the specific material index for mat structure ($\rho_c/E_c^{1/3}$). Due to the fact that increase in E_c from volume fraction enhancement is reduced by the power of $1/3$, increase in density will counterbalance the improvement of the tensile modulus, reverse the increment of the material index of the flax mat-PP composite, and finally lead to higher mass and higher life cycle CO₂ emissions.

Conclusions

This study evaluated multiple impact categories of flax FRPs compared with GFRP based on LCA for automotive application, incorporating generalized ROM and the Ashby method. Under the equal stiffness criterion, the life cycle impact of the flax mat-PP demonstrates a lower environmental impact than glass fiber-mat in most of the impact categories. Such benefits are due to a reduced fuel consumption during the use phase, which can be attributed to the lightweight structure of the flax mat-PP under equal functional stiffness condition. However, flax mat-PP composites suffer from environmental issues common to agro-products. This results in higher impacts in marine eutrophication and freshwater ecotoxicity, due to the nutrients in fertilizers and pesticide compounds respectively. Flax mat-PP composites also stress the availability of arable land area, resulting in a substantially larger agricultural land occupation impact compared with the equivalent glass mat-PP composites. The LCA study for the other analyzed flax FRPs, that is the short flax fiber-PP, leads to different conclusions. The short flax fiber-PP, applied in a strut structure produced via injection molding, requires nearly the same mass as the corresponding short glass fiber-PP composite for the equivalent functionality according to the stiffness criterion. Therefore, the total life cycle impact is very similar for the dominant impact categories when comparing the short flax fiber-PP to its short glass fiber-PP equivalent design.

This study further evaluates the influence of the fiber volume fraction, which is the critical parameter determining the mechanical properties and mass of the composite, on the life cycle environmental impact of the flax FRPs. The results yielded different patterns: The flax mat-PP composite exhibits the optimal volume fractions between 28% v/v and 32% v/v with the minimal life cycle CO₂ emissions as the main target; the short flax fiber-PP, on the other hand, shows steady decreased life cycle CO₂ emissions. Further analysis for flax FRPs from an environmental impact perspective is recommended. Another issue is the impact of surface treatment methods on flax fibers. The LCA analysis should be extended to characterize the environmental impact profiles of different chemical treatment scenarios. Furthermore, this study provides an LCA study for flax FRPs composed with conventional PP polymer. Future analysis is recommended to focus on biobased polymeric matrix solutions from both the functional and environmental impact perspectives.

Recycling of Lithium From Li-ion Batteries

Bhuvaneshwari Balasubramaniam, Narendra Singh, Swati Verma, and Raju K Gupta, Indian Institute of Technology Kanpur, Kanpur, India

Introduction

Batteries are used in many different applications including cars, radios, laptops, mobile phones, and watches. Batteries are classified as primary batteries and secondary batteries. The former one is known as alkaline batteries made up of zinc and manganese as primary source and mainly used for household purposes, which convert automatically chemical energy into electrical energy. The later one is usually made up of nickel (Ni), cadmium, nickel metal hydride or lithium ion and are mainly used in mobile phones, electronic items, cameras, etc. Primary batteries are not rechargeable, while the secondary batteries are rechargeable. The main concern of using batteries is the threat to the environment at the end of its usage. Among all type of batteries, Lithium ion batteries (LIBs) are gaining world-wide interest owing to use in almost all the modern life applications. Experimentation were started by Gilbert Newton Lewis in 1912 over the use of LIBs. After that disposable (primary) LIBs were developed in 1950s. Panasonic is the first company, which produced commercial primary LIBs in 1970. LIBs, a rechargeable secondary battery was first explored in 1970s by M.S. Whittingham at Exxon, which was made of titanium disulfide cathode and a lithium-aluminum anode. Since the instability of metallic lithium presented in that batteries caused safety risk, focus was primarily concentrated on the use of LiCoO_2 and carbon as the cathode and anode materials, respectively (Fey and Huang, 1999). Then, the LIBs were commercially rolled out by Sony at Japan in 1991. The significant role of electrical energy storage technologies demand for green and sustainable energy (Liu *et al.*, 2016). The chemical reactions that take place inside LIB during charging are shown in Eqs. (1–2). Further, the reverse reactions occur during discharge.

LIBs are generally used in portable electronic devices and electric vehicles (EV) due to their high energy density, low self-discharge efficiency, long storage life, light weight, non-memory effect, having wide range of application temperatures, small volume, and advantages in environmentally compatible operations (Zheng *et al.*, 2018; Li *et al.*, 2016; Guo *et al.*, 2016; Wang *et al.*, 2016; Santana *et al.*, 2017; Yao *et al.*, 2016; Xu *et al.*, 2008). The major advantage of these batteries is that they possess higher energy density (W/kg) compared to other battery chemistries being used currently. LIBs presence in the market is from the year 1990 onwards, since the demand of LIBs in electrochemical power sources such as portable electronics and electric vehicles are unavoidable, it is extremely important to come out with the proper recycling methods as it also avoids the environmental pollution due to dumping of heavy metals and toxic chemicals of spent LIBs (Zheng *et al.*, 2018). Also, it saves the energy by giving them second life until their potential is completely utilized. Nowadays, hazardous mixing is a major threat for all the living species as the exposure to pollutants are highly assured due to less care on the environment. Due to this, severe health problems are witnessed, which consequently reduces the life span of people, animals, etc. Hence, recycling of batteries is very much required to protect environment and human health. In the modern era, an efficient harvest, management and storage are three essential segments to energy consumption. Fig. 1 explains about the life history of Li in the battery applications (Winter *et al.*, 2018).

Serious environmental pollution such as the infiltration of toxic heavy metals would occur in the underground water bodies due to the disposal of spent LIBs. On the other side, considerable amount of poisonous gases, such as hydrogen fluoride (HF) will be produced to the atmosphere. This will pollute the atmosphere while burning the spent LIBs. Hence, it is required to come out with a green treatment method which should also bring economic benefits for the recycling of spent LIBs. Due to the presence of larger amount of valuable metals, spent LIBs receive greater attention on commercial aspect (Dorella and Mansur, 2007). The composition of spent LIBs generally are in the range of cobalt (Co) 5%–20%, nickel (Ni) 5%–10%, lithium (Li) 5%–7%, other metals such as copper (Cu), aluminum (Al), iron (Fe), etc., (5%–10%), and the rest are 15% organic compounds and 7% plastic (Ordoñez *et al.*, 2016). However, spent LIBs compositions vary from different sources depending on the manufacturer. The company ZSW has come out with the data of stock and new registrations of battery-electric vehicles. Data reveals that globally, USA and China are in forefront for the development of EV (Huang *et al.*, 2018; Anderson, 2011). The estimated global demand for LIBs is forecasted as per Table 1.

Structure of LIBs and Spent LIBs

LIBs are defined as greener and cleaner energy storage devices compared to other batteries due to their higher voltage, high energy density, low self-discharge efficiency, and less harmfulness to the environment. The constituents of LIBs are generally cathode and anode materials, separator, electrolyte, etc. Among these, the cathode assembly usually contains Al foil (collector), carbon black,

Fig. 1 Life history of Lithium in the battery applications. Reprinted with permission from Winter, M., Barnett, B., Xu, K., 2018. Before Li ion batteries. *Chemical Reviews* 118, 11433–11456.

Table 1 Estimated global forecast for requirement of LIBs

Estimated Year	Product	Estimate (t/year)	Reference
2015	Li ₂ CO ₃ with the battery grade	111,700	(Mohr <i>et al.</i> , 2012)
2050	Lithium exclusively for EV batteries	400,000	(Mohr <i>et al.</i> , 2012)
2020	Lithium ion batteries	21,000	(Anderson, 2011)
2020	Lithium carbonate	40,000–95,000	(Haber, 2008)

Polyvinylidene fluoride (PVDF) as binder, and the anode mainly contains Cu foil (collector), graphite and PVDF binder. The challenge is mainly on recovering the maximum number of valuables out of the minimum number of reagents used. Data shows that 4000 tonnes (t) of spent LIBs contain 1100 t of heavy metals and more than 200 t of toxic electrolyte (Ordoñez *et al.*, 2016). **Fig. 2** illustrates the schematic diagram of the Li intercalation–de-intercalation reaction mechanism in a rechargeable LIB containing solid electrodes and a liquid electrolyte (Roy and Srivastava, 2015).

Applications of Batteries

The LIBs are mainly used in electric cars due to their light weight nature and high energy density as battery packs, cell phone towers, and electronic gadgets like mobile phone, cameras etc.

Statistics and Legislation of LIBs

Data reveals that the production of LIBs has reached 500 million units in 2000 worldwide and in 2010, it is almost 4.6 billion units. The production of the LIBs in China has come to 5.287 billion units in 2014 (Li *et al.*, 2013; Shin *et al.*, 2005; Jha *et al.*, 2013). The greater the number of LIBs being produced; the more spent LIBs will be generated, which need to be recycled. Statistics explained that the lifetime of LIBs used in digital products will only be one to three years and the same will be five to eight years for the power vehicles (Contestabile *et al.*, 2001; Zheng *et al.*, 2018). According to these statistics, by 2020 it is expected that China will produce 2.5 billion of spent LIBs with a mass of about 500,000 t (Zeng *et al.*, 2014).

According to the available report, a directive for collection and recycling of batteries is introduced by European Union. Collection rate of 25% and 45% was targeted for all the batteries sold in 2012 and 2016, respectively. At least 50% of them needs to be recycled from the batteries collected. LIB recycling is carried out in North America, Asia and Europe only.

Fig. 2 Schematic diagram of the lithium intercalation–de-intercalation reaction mechanism in a rechargeable lithium-ion battery containing solid electrodes and a liquid electrolyte. Reprinted with permission from Roy, P., Srivastava, S.K., 2015. Nanostructured anode materials for lithium ion batteries. *Journal of Materials Chemistry A* 3, 2454–2484.

However, the drawback of this collective recycling facilities is capability of treating less than 30% of the world's LIB production.

Benefits of Recycling of LIBs

Environmental Protection Agency (EPA) states that, “batteries contain heavy metals such as lead, cadmium, mercury, and Ni”, which can harm the environment due to improper disposal of batteries (Sun and Qiu, 2011). The spent LIBs usually consist of large amounts of valuable metals such as Co, Mn, Fe, Li, etc. Although, the presence of metal contents is higher than natural ores in the spent LIBs, however, these are recognized as typical hazardous solid waste as these contain toxic metals as well as corrosive electrolytes. Dumping of waste LIBs in landfill sites contaminates the soil. Leakage of the organic electrolyte and the heavy metals causes serious threats to the environment. Recycling of spent LIBs is a preservation and recovery of valuable resources according to the environmental point of view. Thus, recycling of spent LIBs is highly desirable. Hence, the challenges and benefits on recycling spent LIBs highly depend on the finding green and effective way of recovering the valuable metals. There should be emerging technical resources to measure discards, find solutions and safe guard the environment. Government should enforce strict environmental rules over battery recycling to safeguard the environment from dumping of harmful metals arising from spent LIBs.

Fig. 3 illustrates the recycling of spent LIBs from different sources.

Techniques for Recovery of Li From LIBs

Li is extracted from the primary sources like mineral/clay and brines as well as from the secondary sources (LIBs). LIBs are a huge waste across the world, which will increase the health risk of humans, animals, etc. Recovering Li and other valuable metals from these waste batteries will avoid the risk of environment pollution as well as will have advantage at economic level. There are different processes to recover the heavy metals.

Apart from the highly valuable metals such as Li, Ni, and Co, but also Fe, Al, P, and other elements with low recovery values are present in the spent LIBs. Recently, many researchers have come out with the state-of-the-art processes for the metal recovery through recycling from spent LIBs which are basically divided into three types such as pretreatment processes, metal- extraction processes, and product preparation processes (Zeng et al., 2014; Ordoñez et al., 2016).

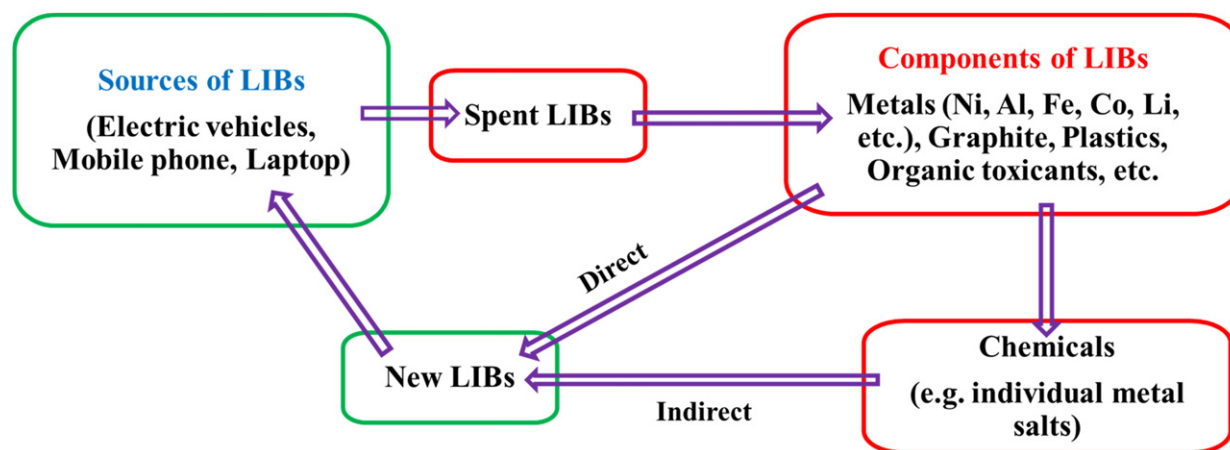

Fig. 3 Recycling of spent LIBs from different sources.

Fig. 4 Classification of Lithium-ion battery recycling process.

Pretreatment Processes

In the pretreatment process, the spent LIBs undergo manual dismantling or mechanical separation process. This helps in segregation of cathode, anode and other components (Zheng *et al.*, 2018). After that the separated constituents are taken for metal- extraction process. Since the cathode material is basically adhered to aluminum foil, separating the cathode from the foil is very difficult. In order to effectively separate the cathode material from foil, different methods such as solvent dissolution method (Yang *et al.*, 2015; Yao *et al.*, 2015; Song *et al.*, 2013), ultrasonic-assisted separation, sodium hydroxide (NaOH) dissolution method (Chen *et al.*, 2011; Ferreira *et al.*, 2009; Nan *et al.*, 2005, 2006), mechanical method (Zhang *et al.*, 2013, 2014) and thermal treatment method (Yang *et al.*, 2016; Hanisch *et al.*, 2015; Sun and Qiu, 2011) are implemented.

Metal Extraction Processes

Metal extraction processes are the most important method to recover the valuable metals (Li, Co, Mn, etc.). Most commonly procedures essentially are (i) Hydrometallurgy, (ii) Pyro-metallurgy, (iii) Biometallurgy, and (iv) Other process for the valuable metal recovery from the spent Li ion batteries (Swain, 2017). These processes have different steps to get Li from spent LIBs as shown in Fig. 4. We will now discuss various processes in detail.

Hydrometallurgy

The metals were leached from the spent LIBs usually using the hydrochloric acid (Zhang *et al.*, 1998; Joulié *et al.*, 2014; Barik *et al.*, 2017; Takacova *et al.*, 2016); sulfuric acid (Joulié *et al.*, 2014; Chen *et al.*, 2015a); phosphoric acid (Pinna *et al.*, 2017; Chen *et al.*, 2017) and nitric acid (Joulié *et al.*, 2014; Lee and Rhee, 2002) etc. The metals (Co, Mn, etc.) were reduced from the high valent state (in solid phase) to easily soluble Co^{+2} , Mn^{2+} , etc., using reducing agents e.g., hydrogen peroxide, sodium carbonate, etc. The metal removal efficiency was affected by the temperature, reaction time, type of leachants, concentration of leachants and reducing agents and solid to liquid ratio.

Zhang *et al.* separated and recovered the valuable metals (e.g., Co and Li) from the spent LIBs. They also examined the effect of leachant concentration, different leachants (e.g., hydrochloric acid, hydroxylamine hydrochloride, sulfurous acid, etc.), solid to liquid ratio, temperature and reaction time for the removal of Co and Li (Zhang *et al.*, 1998). Hydrochloric acid was found to be the best leachant, which recovered 99% of Co and Li using 4 M HCl solution at 80°C for 1 h reaction (Zhang *et al.*, 1998). Co was extracted by the solvent extraction and in sequence Li was precipitate as carbonate (Zhang *et al.*, 1998). The separation and selective removal of Ni and Li was carried out from LiNiO_2 based LIBs. The PC-88A was used as a commercial extractant for the recovery of Ni and Li was recovered in form of lithium carbonate via precipitation using Na_2CO_3 (Nguyen *et al.*, 2015). Similarly, Lee *et al.* extracted Li from LiCoO_2 using oxalic acid leachant. They suggested that leachants like hydrochloric acid, sulfuric acid etc., leaches both Co and Li in the solution and add complication towards the recovery of pure Li. Oxalic acid could selectively recover/leach Li at low pH range. Li was recovered with less than 1% Co leaching as impurity. The leached Co (1%) could be precipitated in the form of Cobalt oxalate. The process was able to recover 90% Li from the LIBs at the optimum conditions. The Li ion in the solution can be transformed into Li_2CO_3 using Na_2CO_3 , after recovering of Co (Lee *et al.*, 2004).

Pyrometallurgy

A typical pyrometallurgy process is a high temperature, smelting and reduction process for the recovery of metals from the spent LIBs. The reduced valuable metals were then recovered in the form of the alloy (Zheng *et al.*, 2018, 2017). Pyrometallurgy processes are mainly focused on the recovery of the other metals (Co, Ni, etc.), while Li was lost in the slag owing to its high reactivity (Zheng *et al.*, 2017). In this process, spent LIBs were directly burned in the smelted furnace, where plastics, graphite and organic components were combusted. The metals were found in the alloy form, which were further purified using leachants and solvent extraction (Zheng *et al.*, 2018). This process results in loss of Li recovery. So, researchers have combined pyrometallurgy process with hydrometallurgy or other processes.

Li *et al.* proposed the “waste + waste → Resources” approach (Li *et al.*, 2016). The anodic materials of graphite were utilized to reduce the cathodic materials of LiCoO_2 under the oxygen free conditions. The reaction was carried out at 1000°C for 30 min under the nitrogen atmosphere separately. The residue consisted of mixture of Co, Li_2CO_3 and graphite. The following reactions might be happening during oxygen free environment (Li *et al.*, 2016).

The residue mixture was further separated by the wet magnetic separation. The recovery of Co, Li and graphite were found to be 97.52%, 98.93% and 91.05%, respectively (Li *et al.*, 2016). Similarly, Hu *et al.* presented a recovery of valuables from the cathodic materials $\text{LiNi}_x\text{Co}_y\text{Mn}_z\text{O}_2$. Al was recovered via the alkaline leaching in the form of NaAlO_2 . The residue was further undergone reduction roasting followed by the carbonated water and sulfuric acid leaching. The reduction roasting was found to be optimum at 650°C for 3 h with 19 wt% carbon dosage and materials were transformed into Li_2CO_3 , Co, Ni, and MnO. The residue mixture was further treated with carbonate water leaching (20 mL min^{-1} CO_2 , solid to liquid ratio 1:10, reaction time 2 h) to recover Li and acid leaching (H_2SO_4) of concentration 3.5 mol L^{-1} at 85°C for 3 h to recover the metals (Ni, Co, Mn). The recovery of Li was found to be 84.7%, while Ni, Co, and Mn were 99% leached out by this process (Hu *et al.*, 2017). In another work, Xiao *et al.* showed the mechanical separation of mixed electrode materials from the spent LIBs containing binder, graphite and LiMn_2O_4 followed by the oxygen free roasting of the mixed metal materials. In this process, binder was decomposed into the gaseous products, while MnO and Li_2CO_3 were formed in the oxygen free roasting at 1073K for 45 min. 91.3% Li was leached in the form of Li_2CO_3 from the roasted powder. Filtered residue was burnt in the air to get Mn_3O_4 and remove graphite (Xiao *et al.*, 2017). Träger *et al.* (2015) combined the mechanical pre-treatment process with the pyrometallurgical process to recover the valuable components of batteries, while these pyrometallurgical process was carried out to recover Li at higher than 1400°C, makes it a high energy consumption process. Georgi-Maschler *et al.* proposed a process to recover all the spent batteries components using the combination of mechanical pre-treatment with pyro and hydrometallurgy. Co alloys and Li_2CO_3 were the main products after the process (Georgi-Maschler *et al.*, 2012).

Biometallurgy

Biometallurgical processes require less equipment, environment friendly besides being a low-cost and high efficiency process. These processes can be promising alternatives than the pyrometallurgy and hydrometallurgy processes. In typical biometallurgy process, the bacteria produces organic and inorganic acids to leach the valuable metals from the spent batteries (Zeng *et al.*, 2014). Horah *et al.* used the fungal activities of *Aspergillus niger* for the bioleaching of the spent LIBs. The citric acid was found to be important for the effective leaching compared to other produced organic acids (gluconic, malic and oxalic acid). The process was conducted in three types i.e., one step (suspension containing battery powder was inoculated in sucrose medium for 30 days), two step (fungi was pre-cultured in sucrose medium for 3 days, which enters in the logarithmic phase after that battery powder was added for 27 days), and spent medium process (A. niger was first cultivated for 14 days, which enters in stationary phase and after that battery powder was added for 16 days). The spent medium process showed high recovery (100% Cu, 95% Li, 38% Ni, 65% Al, 70% Mn and 45% Co), while one step process showed leaching of 100% Li, 11% Cu and 8% Mn with negligible Ni and two-step process showed 100% Li, 61% Al, 10% Mn, 6% Cu and 1% Co leaching with negligible Ni (Horeh *et al.*, 2016). In another work, *Acidithiobacillus ferrooxidans* and *Acidithiobacillus thiooxidans* were used for the removal of metals from the spent LIBs. 99.2% Li, 50.4% Co and 89.4% Ni were recovered under the optimum conditions (iron sulfate = 36.7 g L⁻¹, sulfur = 5.0 g L⁻¹, initial pH=1.5, best inoculum ratio of *Acidithiobacillus ferrooxidans*/*Acidithiobacillus thiooxidans* = 3/2) (Heydarian *et al.*, 2018). Mishra *et al.* utilized *Acidithiobacillus ferrooxidans* bacteria for the bioleaching of LIBs containing LiCoO₂, which provided the elemental sulfur and ferrous ion to produce sulfuric acid and ferric ion in the leaching medium. It has been found that Co showed faster leaching compared to Li, but slower dissolution for Li than Co (Mishra *et al.*, 2008). Xin *et al.* investigated mixed culture of sulfur-oxidizing and iron-oxidizing bacteria for the bioleaching of the spent LIBs using different systems i.e., S, FeS₂, and S+FeS₂. The bioleaching of Li was independent of energy sources, and mainly driven by acid dissolution mechanism. The bioleaching Co was favored by the collective action of acid dissolution and Fe²⁺ reduction in FeS₂ and S+FeS₂ systems, while the acid dissolution was the main mechanism for the S system (Xin *et al.*, 2009). The *Acidithiobacillus thiooxidans* and *Leptospirillum ferriphilum* were used for the bioleaching of metals (Li, Ni, Mn, Co) from the spent LIBs (LiFePO₄, LiMn₂O₄ and LiNi_xCo_yMn_{1-x-y}O₂ based batteries) and showed high recovery of metals (Xin *et al.*, 2016). Li recovery was maximum in the case of sulfur *Acidithiobacillus thiooxidans* system owing to the biogenic H₂SO₄, while other metals were recovered in the mixed energy source and mixed culture systems. The recovery of other metals (Co, Ni, Mn) was driven by the acid dissolution and Fe²⁺ reduction (Xin *et al.*, 2016). Niu *et al.* investigated the bioleaching behavior utilizing *alicyclobacillus* sp. (sulfur-oxidizing) and *Sulfobacillus* sp. (iron-oxidizing) bacteria's. The bioleaching efficiency was affected by the pulp density. 2% pulp density showed the maximum removal efficiency of 89% and 72% for Li and Co, respectively (Niu *et al.*, 2014). The bioleaching efficiency was decreased from 52% to 10% and 80%–37% for Co and Li, respectively with increasing pulp density from 1% to 4% (Niu *et al.*, 2014).

Other Processes

Pyrometallurgy and hydrometallurgy are the main processes to recover the valuable metals from the spent LIBs. Pyrometallurgy is high energy consumption and high metal loss process, and environments hazards are produced in the form of gases and dust. The hydrometallurgy process requires high quantity of chemicals. In the recent years, researcher have started new processes for the recovery of valuable metals (Zheng *et al.*, 2018).

Wang *et al.* achieved Co and Li recovery via mechanochemically. LiCoO₂ materials were first ball-milled with some additives, followed by water leaching procedure and subsequently recovery of Li and Co in the form of Li₂CO₃ and Co₃O₄ by chemical precipitation process. The ethylenediaminetetraacetic acid (EDTA) was found to be the best additive for the extraction of valuable metals. After ball milling, Li-EDTA and Co-EDTA were formed by solid-solid reaction owing to lone pair electrons (two nitrogen atoms and four hydroxyl oxygen atoms) of EDTA, which can enter the empty orbitals of Co and Li. Li-EDTA and Co-EDTA were easily recovered via water leaching. 98% Co and 99% Li could be recovered under the optimum conditions (LiCoO₂/EDTA mass ratio = 1:4, ball milling time = 4 h, rotary speed of ball mill 600 rpm, and ball/powder mass ratio = 80:1) (Wang *et al.*, 2016). Saeki *et al.* investigated Li and Co recovery via grinding with polyvinylchloride (PVC) using planetary ball mill. Li and Co were transformed into the respective chlorides, which were leached out using water to recover Li and Co. The Co and Li yields were increased to 90% after 30 h of grinding. The following reaction takes place during the mechanochemical process (Saeki *et al.*, 2004).

Wang *et al.* used PVC and other additives (Fe, Fe₂O₃, KOH, and many more) for the grinding of LiCoO₂. The ground mixture consisted of Li in the form of LiCl, Co in the form of magnetically separable CoFe_xO_y. Li was 100% converted into LiCl with the zero-valent Fe additive (Wang *et al.*, 2017). Liu *et al.* treated LiCoO₂ (spent from LIBs) and PVC by the subcritical water oxidation, where PVC acts as hydrochloric acid for the metal leaching. 95% Co and 98% Li were extracted from the spent LIBs under the optimum conditions (reaction temperature = 350°C, time = 30 min, PVC/LiCoO₂ ratio = 3:1, solid/liquid ratio = 16:1 in g L⁻¹) (Liu and Zhang 2016). Yang *et al.* targeted Li and Fe extraction from the spent LiFePO₄ batteries through the combination of mechanochemical process and H₃PO₄ leaching. 97.67% Fe and 94.29% Li were recovered from the spent LIBs at the end of the process. The leached metals were further extracted by selective precipitation and overall 93.05% Fe and 82.55% Li were recovered in the form of FePO₄·2H₂O and Li₃PO₄ (Yang *et al.*, 2017).

Table 2 contains consolidated data on the materials recovered from the spent LIBs.

Table 2 Consolidated data over the materials recovered from spent LIBs

S. No.	Recovery Conditions	Materials Recycled	Recovery	References
Hydrometallurgy				
1	Hydrochloric acid	Co and Li	99% of Co and Li	(Zhang <i>et al.</i> , 1998)
	PC-88A	Ni and Li	–	(Nguyen <i>et al.</i> , 2015)

		Co and Li	95% of Co and 98% of Li	(Liu and Zhang, 2016)
		Fe and Li	93.05% of Fe and 82.55% of Li	(Yang <i>et al.</i> , 2017)

Post Treatment (Product Preparation)

The Products can be prepared via many ways. The valuable metal salts have been recovered by the biometallurgy, hydrometallurgy, pyrometallurgy etc., which usually consist of different metal salts/ions. The metal salts can be separated by different processes such as solvent extraction, floatation, chemical precipitation, etc., to get the individual metal salts. In other methods, the cathode material precursor can also be directly prepared through proper solution composition.

Different metal ions were collected in leachate form at the end of metal extraction process. These are separated by different processes such as solvent extraction, floatation, crystallization, etc. Many authors have implemented several techniques to recover CoSO₄ (Ferreira *et al.*, 2009); Cu, Co, Mn, Ni, and Li from spent LIB leachate (Chen *et al.*, 2015b); Li, Fe, and Mn from mixed cathode materials (combined LiMn₂O₄ and LiFePO₄) (Huang *et al.*, 2016). However, it is reported that due to the involvement of large amounts of chemical reagents used in the recovery process, the recovered product is not pure enough. In the case of preparation of precursors for cathode materials, direct preparation methods are followed to avoid complicated separation processes through fine tuning the composition of the leaching solution (Zheng *et al.*, 2018). Further, as obtained cathode material was processed further through co-precipitation (Sa *et al.*, 2015; Krüger *et al.*, 2014) and sol–gel (Yao *et al.*, 2015, 2016) to regenerate the same.

Conclusion

In this article, we have reviewed about the recycling of LIBs. We have discussed in-detail about the type of components present in the spent LIBs and their recycling processes to recover valuable metals. Statistics and legislation of LIBs are discussed as well and benefits of recycling of LIBs are brought out briefly. Green and affordable recycling process is essential to safeguard the environment from heavy metal contamination present in the spent LIBs. Further, effective recycling of spent LIBs will bring down the cost of the raw materials and will help in improving economics at the industrial scale.

Introduction

It is estimated that about 8.3 billion metric tons (Mt) of virgin plastics have been produced to date (Geyer *et al.*, 2017), and 348 Million Mt of these were produced in 2017 (Plastics Europe, 2018). Therefore, it is clear that plastics are one of the most produced manmade materials. Since the discovery of polystyrene in 1839, there has been an exponential increase in research, development, production, and utilization of plastics. Recent advances in plastic production has increased versatility, and they are thus extensively used in a wide range of sectors, from food packaging to automotive, pharmacy, and medicine. Plastics are no doubt an indispensable material of the 21st century and have several benefits to which few alternatives exist. For example applications such as packaging, electronics, building and construction as well as agriculture have considerably benefited from plastics and in turn supported human development and growth by preserving produce, shaping global communications, and enhancing economic growth.

Although plastics can be reused, recycled, upcycled, or incinerated for energy recovery, a significant proportion of plastics still pose an environmental challenge because of poor disposal rates. Statistics tracking the destination of plastics reveal that only 9% of all global production has ever been recycled; 12% was incinerated, with the majority, 79%, accumulated in landfills or the natural environment (Geyer *et al.*, 2017). Plastics need several hundred years to biodegrade, which means the landfill sites are going to be a considerable environmental challenge for generations. Though the data suggests that with increased awareness of the dangers of leaving plastics in landfill, recycling and upcycling are becoming mainstream activities in many parts of the world, as recycling rates have increased over the last few decades.

Similarly, the improper disposal of plastics has had an adverse effect on marine life; this is becoming a key part of the environmental discourse, leading to significant action from environmental groups and increasing activity from nongovernment actors protecting marine life and raising awareness about the dangers of plastic waste.

These environmental challenges of sustainably disposing plastic waste are exacerbated in Low and Middle Income Countries (LMICs), particularly those in areas with poor infrastructure and weak institutions, which have inadequate waste management systems. A fairly common sight in these communities is plastic litter around the community, as illustrated in Fig. 1. The need for improved plastic waste management in LMICs becomes even more important when it is recognized that over 60% of the plastic production and consumption occurs in LMIC predominated regions: Asia, Africa, and Latin America (Plastics Europe, 2018).

In informal ecosystems, waste pickers typically drive the recovery of postconsumer waste; plastics are collected, sorted, pre-processed, and sold to plastic recyclers. This informal waste economy is quite vibrant in many LMICs and relies on the lack of coordinated waste management systems. Reusing plastic waste is also common in LMICs, for example, using plastic bottles, for storing cooking oils, portable water, and kerosene. However, these informal methods of plastic waste management are restricted to certain types of plastics and driven by demand.

An interesting development in upcycling plastic waste is the relation between low cost building construction materials and the huge demand for adequate housing in LMICs. Rapid urbanization taking place in LMICs has led to a shortage of housing in major cities, and consequently resulted in formation of informal settlements by the urban poor. The urgent need to provide homes for this population is a challenge because often resources are limited. It has been suggested that affordable and sustainable homes should employ suitable, locally sourced material and resources (Oyinlola *et al.*, 2018). Since plastic waste is often in abundance

Fig. 1 Plastic waste in low income community in Paipe.

and versatile, there is a strong case for it to be the candidate material for constructing affordable sustainable homes. Utilizing waste plastics in this form could be a driver for the development of the informal circular economy as it could place a higher premium on these waste streams. This has implications for reshaping the circular economy and incentivizing community members to partake in sustainable waste management practices.

This article explores the use of plastic waste in building construction, especially for low income homes, it reviews the different types and ways plastics have been used in construction, as well as presents some performance data. It further highlights the benefits and concerns of using plastics in low cost construction.

Plastics in Construction

Several researchers and professionals have explored the possibility of using waste plastics in constructions. This section highlights most of the common ways plastics have been used for construction.

PET Bottles as Building Bricks

Polyethylene terephthalate (PET) bottles make up a significant proportion of the plastic waste stream due to their increased use in the food and beverage sector. The opportunity to fill them up with other materials has made them an attractive option for use in low cost construction globally. There have been reports on this concept in various countries such as Nigeria, South Africa, Philippines, Norway, and India. Common names for this concept include bottle house, bottle bricks, and eco bricks.

The methods adopted for using PET bottles in construction vary from project to project. For example, plastic bottles can be filled with one or more materials such as sand, soil, and/or plastic bags. The filled bottles could be used directly as a brick or embedded inside blocks made from cement or clay. However, it is worth noting that the mortar used to hold the bottles in place varies across projects and plays an important role in the loading capacity of the wall.

Many reports of using plastic bottles have been made on websites and social media, however, few researchers have scientifically studied the suitability of plastic bottles as a candidate material for constructing low cost, environmentally-friendly homes. These studies usually focused on characterizing the mechanical, structural, and thermal properties of these materials.

In Bangladesh, [Muyen et al. \(2016\)](#) studied the structural and thermal behavior of plastic bottles filled with dry sand, saturated sand, or air. They examined the effect of bottle size (250, 500, 1250, 1500, and 2000 ml) in three types of cement mortar based samples: Cubes, bricks, and cylinders. They found that plastic bottles filled with sand have the highest compressive strength of up to 35 MPa. They also noted that the compressive strength increased with the size of the bottle. Although the strength of the plastic bottle wall was considerably less than conventional bricks, they suggested that they could still be used as a suitable building material. They noted that air filled bottles showed better thermal insulation than traditional blocks.

In India, [Rawat and Kansal \(2014\)](#) performed a series of compression tests on 600 ml soil filled bottles and found them to have an average strength of 8.99 MPa. They further stated that compared with local bricks, PET bottles have an added advantage of improved ductility and inhibition of crack propagation after its initial formation. They also found PET bottles to be more cost effective, energy efficient, and feasible compared with using standard bricks. [Mokhtar et al. \(2015\)](#) also studied the compressive strength and obtained better results. Their tests using 250 ml and 1.5 l bottles, filled with partially wet sands gave a value of 38.34 MPa and 27.39 MPa respectively.

[Oyinlola et al. \(2018\)](#) measured the compressive strength of two types of mortar mixes used when constructing the bottle house shown in [Fig. 2](#). The mortar of the first sample was made of 1:4:5 ratio of cement, clay soil, and river sand respectively. Water was used to mix for good workability. The mortar for the second sample was a 1:9 mixture of cement and sand with water. Experimental testing showed that the sample with clay had a compressive strength of 0.6 MPa while a compressive strength of 1.2 MPa

Fig. 2 Bottle house in Paipé, Abuja, Nigeria. Reproduced from Oyinlola, M.A., Whitehead, T., Abuzeinab, A., et al., 2018. Bottle house: A case study of transdisciplinary research for tackling global challenges. *Habitat International* 79, 18–29. doi:[10.1016/j.habitatint.2018.07.007](https://doi.org/10.1016/j.habitatint.2018.07.007).

was observed in the mortar mix without clay. They also gave a detailed description of how the bottles were used in construction. The bottles were laid horizontally on the ground with a spacing of about 4 cm. PET bottles were then knitted into a matrix using a rope; the rope went over a bottle and linked to the adjacent bottle in a repeated fashion. The ropes helped to hold the bottles in place before the mortar was applied and acted as a fiber reinforcement for the mortar, thus increasing the structural integrity and stability.

The examples discussed above highlight the variability in characterizing the strength of plastic bottles, which is affected by various parameters, such as size of bottles, material used for filling, and mortar. However, there is unanimity on the suitability of PET bottles as a suitable material for construction.

PET Aggregates in Concrete

Waste plastics have also been used as an aggregate in construction mortar. The manner in which this is used varies; the plastics could either be ground into smaller particles or cut into strips before being mixed into the mortar. This method of using waste plastic as aggregate is not exclusive to low cost construction and several scholars have reported on utilizing plastic waste as mortar aggregate. PET seems to be a popular candidate for this method.

Aggregates from some types of plastics, especially PET, have been found to mix well with concrete. For example, [Ochi et al. \(2007\)](#) developed concrete-reinforcing PET fiber from used PET bottles; the project team reported good mixing between the fibers and concrete at up to 3% fiber content.

Another advantage of using plastic waste aggregate is that it could enhance the properties of the mortar. For example, [Kim et al. \(2010\)](#) studied the effect of using short fibers made from recycled PET within structural concrete. This study found a significant improvement in the ultimate strength and relative ductility of the PET reinforced beams, compared with those without. Similarly, [Fraternali et al., 2013](#) produced PET strips by simply hand cutting used PET and studied the effect of using this in cement mortar. Similarly this research found that at 1% fiber volume, the reinforcing strips markedly improved the toughness of the cement mortar while [Bui et al. \(2018\)](#) found that up to 9% increase in compressive strength can be achieved when using recycled PET fibers in recycled aggregate concrete.

The properties of plastics have been exploited when used as aggregates. For example, they have been used to produce lightweight concrete ([Alqahtani et al., 2017](#)). Plastics generally have low thermal conductivity, which make them an attractive option for improving the thermal performance of building envelopes ([Poonyakan et al., 2018](#)). Using waste plastics as aggregates has been studied extensively and well documented in the literature. A review of this can be found in [Gu and Ozbakkaloglu \(2016\)](#).

Low Value Plastics

One of the most problematic types of plastic waste is used carrier bags made from polyethylene. These are especially challenging in low income communities because they have little or no value in the informal waste economy. These low value plastic wastes have been used in construction, either unprocessed or processed to make new composite materials. This section highlights some ways low value plastic wastes have been used in construction.

Unprocessed

A few studies have reported using plastic bags as key construction materials. [Taaffe et al. \(2014\)](#) conducted experiments to determine the compression, acoustic, and light transmission properties of plastic bags packed in plastic bottles, which they referred to as eco bricks. The study concluded that eco brick was a viable resource for construction purposes with a number of possible applications. The low thermal conductivity of plastics implies that they provide much better thermal insulation although at a lower strength, they found an average strength of 2.72 MPa. Using low value plastics as a filling material is advantageous for low income communities because this requires little or no specialized skill.

Another innovative use of unprocessed plastic waste was developed by a US-based start-up called Byfusion (see “Relevant Websites section”). The technology developed – Byfusion Blocker – can convert 100% of plastic waste into ByBlocks. This is achieved by superheating shredded plastics and then fusing them into building blocks. The byblocker can use any category of unsorted and unwashed plastic waste. The ByBlocks, though not load bearing, are said to have superior thermal and sound insulation properties when compared with cement based blocks. This method does not require any specialized skills, however, it requires specialized equipment and is suited for large scale recycling in municipalities.

Processed

Another way of using low value plastics is by melting them and mixing the molten plastic with other material such as soil and cement. There have been few reports about using plastics in this way. For example, in Mexico, EcoDom (see “Relevant Websites section”), based in Puebla, has produced building materials such as walls and thermic roof by recycling various types of plastic waste including PET, high-density polyethylene (HDPE), polypropylene, and acrylonitrile butadiene styrene (ABS). Their process includes sorting, grinding into flakes, and pressing at high pressure to form the raw material for their products. The company claims the products have much higher strengths when compared with traditional building materials.

Similarly, *Conceptos Plásticos* (see “Relevant Websites section”), Colombia has built several low cost homes using LEGO-style bricks made from recycled plastics. The plastics are melted and poured into a mold to form the bricks. The molds are designed to

Fig. 3 Process flow diagram showing the method used to produce low-density polyethylene-sand composite materials. Reproduced from Kumi-Larbi, A., Yunana, D., Kamsouloum, P., *et al.*, 2018. Recycling waste plastics in developing countries: Use of low-density polyethylene water sachets to form plastic bonded sand blocks. *Waste Management* 80, 112–118. doi:10.1016/J.WASMAN.2018.09.003.

produce bricks that are simple in structure and can easily slot together. This eliminates the need for using mortar as well as accelerates the construction process, which requires little skill. They report a construction time of 20 man-days for a simple house, and a 30% reduction in cost compared with the traditional construction process.

Kumi-Larbi *et al.* (2018) studied the effect of sand particle size and sand to plastic ratio on density, compressive strength, water adsorption, flexural strength, and thermal conductivity. Their sand block samples were produced using a simple technology that involved mixing sand with melted low-density polyethylene (LDPE) water sachets (which is a cheaper form for packaging purified water) and forming in mold. Fig. 3 shows a process flow diagram of their process. They reported strengths of up to 27 MPa and observed an inverse relationship between the particle size and compressive strength/density.

Benefits of Plastics in Construction

Many studies have reported several benefits of utilizing plastic waste in construction. The most obvious environmental benefit is reducing the amount of plastics that go to landfill. This is very significant as recent studies have shown the negative effects waste plastics are having on life on land and underwater. Utilizing plastics in this way contributes to achieving the United Nations

Sustainable Development Goals, (SDGs) goal 14: life below water and goal 15: life on land. Furthermore since most low income communities in LMICs have weak infrastructure for waste management, utilizing waste plastics for low cost construction places a higher premium on these wastes and can further expand and strengthen the informal waste economy.

Another benefit is the potential to lower construction cost by replacing traditional materials. Most scholars have reported a lower cost, for example [Muyen et al. \(2016\)](#) reported that plastic bottle walls cost approximately 75% less than concrete block walls while [Oyinlola et al. \(2018\)](#) reported a 30% reduction on the total construction costs compared with using traditional cement blocks. It is important to note that the cost of labor in low income communities is relatively cheap, hence, materials make up the bulk of the costs for construction. Furthermore, transport costs are significantly reduced when using available building materials; even the cost of transporting waste plastics to building is relatively cheap, since they are lightweight. Therefore, using locally engineered waste materials can significantly reduce the cost.

Since plastics do not biodegrade for centuries and are impermeable, they can be considered as durable materials for construction. They have improved ductility and can inhibit crack propagation after its initial formation ([Rawat and Kansal, 2014](#)). Also, using plastics can significantly reduce construction waste since they are nonbrittle, compared with using conventional blocks. This also implies they can be reused if a wall is destroyed. The insulating properties of plastic make them an excellent material for improving thermal comfort in home. Claims have been made that walls made from sand filled bottles are bulletproof, fireproof, and earthquake resistant, however, there has been no scientific study to prove this.

Concerns About Plastics in Construction

Despite the numerous benefits of using waste plastics in low cost construction, there are also genuine concerns about their use. This section highlights some of the main concerns that have been raised about using plastics in low cost construction.

User Acceptance

Most of the studies published on using waste plastics in construction have focused on characterizing the mechanical, structural, and/or thermal properties. A glaring gap in the literature is in terms of the user acceptance of this concept in low income communities. [Oyinlola et al. \(2018\)](#) conducted a study to evaluate the user acceptance of a bottle house in Abuja, Nigeria. They noted a generally positive response to the bottle house concept from high and middle income visitors. However, members of the low income community, who could be potential occupants, were not willing to live in the bottle house. Firstly, living in a home built from waste materials would have a negative impact on their social status. Secondly, most of the sustainable measures proposed, such as the roof, would make the house different from contemporary homes in the city, thus less desirable and esthetically unacceptable. The study highlighted how sociocultural and political considerations may trump economic ones; regardless of the benefits of a material, it was important for it to look esthetically contemporary for the concept to be acceptable. This concern can be overcome by using conventional cladding materials or embedding plastics fibers into conventional building materials. However, more studies are needed to understand the barriers and drivers for user acceptability of waste plastics in construction in low income communities.

Social Viability

The informal waste economy is usually strong in low income communities, especially for PET. Plastic waste is usually collected, sorted, preprocessed (washing and grinding into flakes), and sold to plastic recyclers for further processing. Similarly, plastic containers are often reused in these communities for storing things like cooking oil, kerosene, portable water, etc. These realities mean that firstly, since there is a market for some types of plastic waste, utilizing higher value plastics in low cost construction may be challenging and/or counter sustainable, since they are already associated with a particular segment of the circular economy. In-depth lifecycle analyses to compare the environmental and economic value of utilizing waste plastics in construction as against current circular economy uses are needed.

Another concern is the practicality of deploying mechanisms for collecting and sorting plastic waste for constructing several homes. Most reports on low cost construction have been on a small scale, for example, [Oyinlola et al. \(2018\)](#) collected 10,000 PET bottles for a 2-bedroom house. This might be challenging to achieve on a large scale. The peculiarities of deploying them at a large scale need to be further studied. Furthermore, some of the methods of utilizing plastic waste require some level of skills, which might require the need to build local capacity. This can be challenging and time consuming, hence a cost-benefit analysis is essential to determine the long term viability.

The potential health hazards of using plastics in construction are another major concern. Firstly, methods that require melting of plastics are thought to produce fumes that can have a long term negative impact on health. This is especially worrying because of the absence of adequate health and safety mechanisms in LMICs. Another cause for concern is that plastics may be outgassing toxic gases at ambient temperature, which may pose a significant risk to inhabitants of homes built with plastics. This concern needs to be investigated as well as the long term performance of plastic when it is mixed with other building materials or subjected to ambient conditions over extended periods.

Conclusion

Sustainably tackling waste plastics is one of the global challenges of the 21st century and the absence of essential waste management infrastructure in LMICs exacerbates this challenge. However, there is a real opportunity to utilize this resource and help provide adequate housing for low income users, which plays a crucial role in sustainable development.

This article provided an insight into innovative ways waste plastics have been used for providing low cost housing. The properties of plastics make them an attractive material, especially when mixed with other conventional building materials. They have potential to increase strength, improve thermal performance, and provide greater flexibility in construction. Some of the methods commonly employed include using PET bottles as blocks, using them as mortar aggregates, and melting them to produce new building components. Various scholars have characterized the mechanical, structural, and/or thermal performance of plastics in low cost construction, however, there is still a wide gap in the literature in terms of understanding user acceptance, social viability, as well as understanding the long term health implications of using plastics for building homes.

Recycling of Red Mud for Value-Added Applications: A Comprehensive Review

Mostafa Mahinroosta, Zahra Karimi, and Ali Allahverdi, Iran University of Science and Technology, Tehran, Iran

© 2020 Elsevier Inc. All rights reserved.

Introduction

The development of the mineral industries led to the generation of large quantities of waste materials and byproducts which in turn caused various environmental problems. Over the years, the exploitation of mines/quarries has gradually decreased the quality of ores due to the extraction of rich reserves, and as a result, the amount of waste increased. The accumulation of waste, in particular waste from different stages of processing, is one of the major sources of environmental problems. Most of these mineral deposits are hazardous and, directly or indirectly affect the environment. If the waste materials are not properly controlled, their harmful substances enter the surface and underground water and pollute the vast area. Meanwhile, bauxite residue, (known as red mud (RM), red clay, alkaline clay, and cajunite) (World's Leading Producers of Aluminum Oxide, 2017), is considered as one of the environmental concerns (Power *et al.*, 2011). The RM is produced during the Bayer process, the production of alumina from bauxite ore. Due to its small particle size, high alkalinity, and huge volume of production, the RM leads to the environmental crisis (Rao *et al.*, 2016a). The annual production of the global RM is estimated at 120–150 million tons. According to 2007 statistics, more than 2.7 billion tons of RM have been accumulated in different parts of the planet, and this accumulation is still expanding, as today's accumulation is estimated at around 4 billion tons (Marin *et al.*, 2018). An average of about 1–2 tons of RM is produced per ton of alumina production in the Bayer process. The quality of the RM depends on the process conditions and bauxite quality. The main factor in bauxite quality is the nature of alumina hydroxide compounds (gibbsite, boehmite or diasporite) and its silica content. Regarding the dangerous nature of the RM, especially considering its pH value, many discussions have taken place in the European Union. Based on a number of standard criteria, any waste with a pH value higher than 11.5 is often regarded as a hazardous substance (Evans, 2016).

The International Aluminum Institute (2016) proclaimed that just in 2016, China was responsible for 55% of global alumina production, followed for Australia and Brazil with 17% and 9%, respectively. While in 2017, Australia ranked first. It is estimated that more than 85 plants are located around 32 countries, responsible for the alumina production (The International Aluminum Institute, 2016; Tsakiridis *et al.*, 2004). Fig. 1 shows the world's leading producers of aluminum oxide. Rationally, these countries are the largest origins of the RM throughout the world.

Safe disposal of RM as an initial practice is a costly and challenging approach for the alumina manufacturers. On the other hand, adopting an improper disposal method can adversely affect the ecosystem and surface and underground water. If appropriate solutions can be found for the utilization of RM, they will provide multilateral advantages both for environment and industries. First, the amount of the waste and its corresponding disposal cost will decrease. Second, the environmental pollution originated from the waste disposal will remarkably be diminished. And third, the production and development of cost-effective advanced materials from such wastes can result in the conservation of natural resources and also economic benefits. All these together facilitate a sustainable environment and development.

The global tendency for the more efficient exploitation of resources led to many endeavors for the utilization of RM in the past few years. The increase of industry enthusiasm, academic research, and funding by organizations such as the European Union considerably improved the collaboration between academic and industrial communications. In 2015, under the 2020 perspective,

Fig. 1 World's leading producers of aluminum oxide (based on data on 26 Sep. 2017).

Fig. 2 Registered patents between 1964 and 2008 for the applications of red mud.

the European Union agreed to fund 15 PhD graduate for research on the recycle and utilization of RM. Approximately 3.7 million euros were funded for this purpose. The main focus of the research was on the extraction of iron, titanium, aluminum and rare earth elements (such as scandium), and the production of new construction and building materials from RM (Evans, 2016). Despite the acceptable results of utilizing RM in the construction sector, there is still no large scale application to reuse RM, because the studied options did not completely justify the requirements and economic-environmental feasibility of the research plan. Between 1964 and 2008, over 734 patents were registered on the application of the RM (Klauber *et al.*, 2009). As seen in Fig. 2, 34% of the registered patents are assigned to the civil and building construction application of the RM, followed by wastewater treatment, ceramics, and so on. Considering the huge amount of generation and also resulting ecological and safety aspects of the RM, the need for further research on this solid industrial waste is quite evident (Gräfe and Klauber, 2011).

In recent years, public awareness and concerns on the quality of environment forced the legislators to pass strict regulations on environmental contamination due to the industrial wastes. Today, the need to develop economic methods for the utilization of wastes is a necessity, resulting in the great importance of recycling of the remaining valuable materials in the composition of industrial wastes (Klauber *et al.*, 2011).

This review work tries to highlight the various aspects of the RM including its chemical and mineralogical compositions, production process, environmental impacts, with an emphasis on different utilization and recycling methods.

Red Mud Production Process

The RM as the bulky waste of the Bayer alumina production process, is formed as the result of the reaction between sodium hydroxide and bauxite ore. The bauxite ore is usually a combination of minerals rich in aluminum oxide and hydroxide. However, bauxite also contains minerals of iron, silicon, titanium and rare earth elements. For each ton of alumina produced, about 1–2 tons (dry mass) of RM are produced (Wang *et al.*, 2008). Fig. 3 shows a schema of the traditional Bayer alumina manufacturing process.

This process involves the separation of alumina from unwanted components such as iron, titanium, silica, calcium, vanadium, manganese, etc., in bauxite. In this process, bauxite is heated along with the caustic soda at high pressure (~30 atm), resulting in the formation of sodium aluminate (reactions (1)–(4)) (Gil, 2005; Ma *et al.*, 2009).

Aluminate is hydrolyzed and converted to aluminum hydroxide (reaction (5)), followed by the production of aluminum oxide or alumina after calcining the produced aluminum hydroxide at high temperature ($\geq 1200^\circ\text{C}$) (reaction (6)) (Gil, 2005). After extraction, the insoluble residue is known as red mud or bauxite residue. Its color and name are due to its high iron oxide content. For each tone of alumina produced, 2–3 tons of bauxite ore should be used. Depending on the quality of bauxite ore, 1–2 tons of RM waste are also produced as a byproduct (Rai *et al.*, 2017).

Fig. 3 A typical alumina production process (Bayer process).

Table 1 Typical chemical composition of red mud

Major element	Conc. (wt%)	Minor element	Conc. (mg/kg)	Minor element	Conc. (mg/kg)
Fe	4.53–50.10	U	50–60	Mn	86
Al	4.42–16.06	Ga	60–80	Y	60–150
Si	2.16–14.86	V	730	Ni	31
Na	0.98–7.79	Zr	1230	Zn	20
Ca	0.39–16.72	Sc	60–120	Lanthanides	0.1–1
Ti	0.98–5.34	Cr	497	Th	20–30

Characterization of Red Mud

The RM has a specific gravity of 3.0–3.6 g/cm³ (World's Leading Producers of Aluminum Oxide, 2017). A typical chemical composition of the RM, including the major and minor elements, is shown in Table 1. As can be seen, the highest proportion pertains to iron. The amount of iron in various types of RM, depending on the structure of the initial bauxite ore, can range from 4% to 50%. It is possible to achieve an iron recovery efficiency of around 51% in some samples, comparable with iron ore. It is necessary to note that a wide range of other components can be present in trace amounts in bauxite, in particular oxides of As, Be, Cd, Cr, Cu, Ga, Pb, Mn, Hg, Ni, K, Th, V, Zn, Sc, and lanthanide. Some of these elements remain undissolved during the Bayer process, as they are eliminated with the RM, while some are soluble and present in the Bayer leachate or the aluminum hydroxide precipitate. The concentration of these elements in the RM depends on the temperature used in the extraction process. These valuable elements may be recovered using appropriate techniques (Rao et al., 2016a; Marin et al., 2018; Liu and Naidu, 2014; European Aluminium, 2015). A wide variety of organic compounds can also be present in the chemical composition of the RM, originating from organic matter and vegetables in the RM. These are carbohydrates, alcohols, phenols, and sodium salts of polybasic and hydroxyacids such as fulvic, humic, acetic, oxalic or succinic acids. In addition, small quantities of some sodium compounds derived from the sodium hydroxide used in the digestion process, depending on the conditions of the dewatering and the washing system, may remain (European Aluminium, 2015). The bauxite contains very few radioactive elements such as uranium (²³⁸U), thorium (²³²Th and ²³⁴Th), bismuth (²¹⁴Bi and ²¹²Bi), and polonium (²¹⁰Po). The amounts of these elements in the bauxite are naturally in the range of mg/kg and cause very low levels of radioactivity. During the Bayer process, a great part of these elements remain undissolved. Therefore, the concentration of these radioactive species in the RM is higher than that in the initial ore (European Aluminium, 2015; Miller and Miller, 2016; Hegedűs et al., 2018; Gu et al., 2017b).

To find out how the RM can be converted into valuable products, one can look at it from two different standpoints. In the first view, the RM is considered as a mixture of metal oxides and other compounds that exist or can be formed by heating over 1000°C. These components can be utilized to produce different metals such as iron, aluminum, silicon, calcium, titanium and sodium. Such an analysis is performed by X-ray fluorescence (XRF) technique (Klauber et al., 2011). An example of XRF analysis, which is performed on the RM generated in Iran Alumina Company, is presented in Table 2 (Karimi et al., 2018):

In the second view, which is a mineralogical standpoint, X-ray diffractometry (XRD) is employed to characterize the RM as a combination of various minerals (Klauber et al., 2011). As presented in Table 3, the RM has a complex mineralogical composition with a large number of different compounds such as iron-rich phases (hematite, goethite), aluminum (gibbsite, diasporite, bayerite), calcium (calcite, calcium silicate and calcium aluminosilicate) sodium (sodalite, cancrinite, dawsonite), silicon (quartz,

Karimi, Z., Allahverdi, A., Mahinroosta, M., 2018. Recovery of metals from red mud using mineral acids. In: Proceedings of Iran International Aluminium Conference (IIAC2018), 24–25 April 2018. Tehran, Iran.

cancrinite, sodalite) and titanium (rutile, anatase) (Marin *et al.*, 2018; Klauber *et al.*, 2011). Also, in the composition of RM, one percent of the original goethite (α -FeOOH) may turn into hematite (α -Fe₂O₃), depending on the process conditions. Titanium minerals can react with calcium to form perovskite. Sodalite, cancrinite, dawsonite and most of calcium-containing phases are formed as a result of the Bayer process. Boehmite, gibbsite, anatase and rutile, ilmenite, perovskite and quartz are other minerals commonly found in the RM matrix (Gräfe and Klauber, 2011).

For instance, the XRD pattern of an RM sample taken from Iran Alumina Company, is depicted in Fig. 4. As clearly seen, hematite (Fe₂O₃), calcite (CaCO₃), katoite (Ca₃Al₂(SiO₄)(OH)₈), cancrinite (Na₆Ca₂Al₆Si₆O₂₄(CO₃)₂·2H₂O), spurrite (Ca₅(SiO₄)₂CO₃), and rutile (TiO₂) phases have been identified.

The chemical composition estimation based on quantitative calculations of the XRD data can be accomplished through Rietveld analysis. Fig. 5 shows the estimated chemical composition of RM of Iran Alumina Company using the XRD data. As can be seen, the calculated percentages of Al₂O₃, SiO₂, Fe₂O₃, TiO₂, CaO, MgO, and Na₂O are very close to the XRF values listed in Table 2.

Fig. 6 shows field emission scanning electron microscopy (FESEM) images of the RM sample of Iran Alumina Company. As seen, the RM comprises of various particles with different size and shape. In addition, the RM exhibits a relatively porous structure.

The RM is mainly composed of fine particles, but it may also contain small amount of coarse grains. The fine portion typically is 90% by volume below the size of 75 μ m (Singh *et al.*, 1997a; Smirnov and Molchanova, 1997), and a high surface area of between 30 and 50 m²/g (Li and Rutherford, 1996). As an instance, Fig. 7 shows particle size distribution of the RM waste of Iran Alumina Company. As seen, the coarse portion has a size between 1 and 8 μ m. The particle size distribution curve indicates that 50% of the fine portion is below 2.94 μ m, whereas 100% of the portion has a size of less than 24 μ m.

Atun and Hisarli (2000) measured the surface charge of the RM and reported an intense uptake of protons. The zero point of charge (pH_{zpc}) of the RM was obtained about 8.3 in low concentration of sodium, cesium, and strontium chlorides, which very close to the pH_{zpc} values of Al₂O₃, Fe₂O₃, and TiO₂.

Environmental Impacts

The accumulation of hazardous industrial wastes has become a global concern which imposes potentially serious ecological problems (Chaban, 2001). The major strategies currently applied to manage the RM are marine disposal, lagooning, dry stacking,

Fig. 4 XRD pattern of red mud waste of Iran Alumina Company.

Fig. 7 Top: coarse red mud particles, Bottom: particle size distribution curve of fine portion.

and dry cake disposal (Power *et al.*, 2011). The disposal of the RM in open space is challenging for alumina production plants (Rai *et al.*, 2012). The challenge originates from two main drawbacks: (1) due to highly alkaline nature and chemical composition, the RM has an undeniable effect on the environment; and (2) disposal of the RM imposes a large expenditure and needs for vast landfill sites for alumina production industry (Díaz *et al.*, 2015). The disposal cost is about 2%–5% of alumina price (Liu and Zhang, 2011). Fig. 8 shows the latest Google Earth spatial photo of an alumina production plant in Jajarm, Iran, with RM disposal landfill sites in the vicinity of the plant.

The RM is disposed as dry, semi-dry or as slurry in ponds. The slurry contains a high solid concentration of 30%–60% and high ionic strength. Untreated RM has a high pH value ranging from 11 to 13, which makes plant growth impossible and causes serious environmental problems. As illustrated in Fig. 9, the environmental problems caused by the discharge of RM are related to its high pH, leakage of alkali, heavy metals and radionuclides to surface and underground water, safe storage, alkaline dust emissions, and need to vast landfill sites for discharge (Rai *et al.*, 2012).

Due to its high alkalinity, the presence of toxic trace elements (such as Cr, As, Cd, Hg, Ni, etc.) and radionuclides (such as ^{226}Ra , ^{230}Th), the RM can be regarded a hazardous industrial waste (Klauber *et al.*, 2011; Milacic *et al.*, 2012; Kolencsik-Tóth *et al.*, 2014; Sas *et al.*, 2015; Mora *et al.*, 2015). In most cases, alumina companies discard the RM into open-air reservoirs keeping it in a solution of caustic soda (wet storage) and stockpiling large amount of it over decades (Klauber *et al.*, 2011). The wet storage method may bring about a high risk of dam failures (Mora *et al.*, 2015; Grenczky and Wegmüller, 2011; Wen *et al.*, 2016) which can result in severe environmental disasters as it previously taken place in Brazil (Segura *et al.*, 2016) and earlier in Hungary (Szépvölgyi, 2011; Rédey *et al.*, 2013). In 2010 in Hungary, a lagoon containing RM slurry flooded, and about 700,000 m³ of the slurry waste was flowed in the region of Ajka. As a result, 10 people were died, about 350 houses were destructed and significant regions were contaminated (Szépvölgyi, 2011; Rédey *et al.*, 2013).

Regarding its nature, the RM in wet storage mode can be regarded as a complex blend of pollutants. Its broad impacts on soil ecosystem are only partially recognized. The fine particle size (preponderantly less than 20 μm) of the RM can fill the soil pores and perpetually change soil texture. This threatens the life of most of the soil biota groups (Anton *et al.*, 2012; Gruiz *et al.*, 2012; Kovács *et al.*, 2013). Also, the high sodium concentration and strong alkalinity of the RM usually have strong adverse influences on both the below- and the above-ground communities of soil biota (Rékási *et al.*, 2013; Winkler, 2014; Stenchly *et al.*, 2017). In addition, invertebrate soil organisms are also often negatively influenced by the increasing levels of trace metal contamination; however, different groups or species can react distinctively (Hodson, 2013). Despite the threats and potential hazards of an RM

Fig. 8 Google Earth image of red mud storage area in Iran Alumina Company.

Fig. 9 Environmental pollution by red mud via different pathways.

exposure, it has to be noticed that the RM can also decline mobility of such trace elements as Cd, Ni, As, Cu, and Pb in the soil, due to its high alkalinity characteristic and high Al and Fe content (Anton *et al.*, 2012; Garau *et al.*, 2007; Ujaczki *et al.*, 2016b).

Utilization of Red Mud

Over the past several decades a lot of efforts have been made to find environmentally-friendly and cost-effective techniques to utilize the RM. The recycle and reuse of very massive quantities of generated RM have been a significant challenge for the alumina industry all over the world. Moreover, the transportation costs from the alumina refinery to the processing plant is another problem (Klauber *et al.*, 2011; Liu and Naidu, 2014; Samal *et al.*, 2013). To decrease the stockpile of annual produced RM, the utilization should be not only technically applicable and effective but also economically practicable. The future management of this residue and moving it towards zero waste are two tremendous environmental concerns. According to the most important classification shown in Fig. 10, a wide range of research fields have been conducted to develop some methods for effective utilization of RM, including: metal recovery

Fig. 10 The most important methods for utilization of red mud.

(Pepper *et al.*, 2016; Gu *et al.*, 2017a; Yu *et al.*, 2012; Yang *et al.*, 2015; Alkan *et al.*, 2018; Narayanan *et al.*, 2018; Ujaczki *et al.*, 2017a; Borra *et al.*, 2016; Wang *et al.*, 2018b), construction and building materials (Tsakiridis *et al.*, 2004; Liu *et al.*, 2018; Lima *et al.*, 2017; Li *et al.*, 2018; Nikbin *et al.*, 2018; Alam *et al.*, 2017; Scribot *et al.*, 2018; Zhang *et al.*, 2018; Krivenko *et al.*, 2017), low-cost adsorbents for pollutant removal (Li *et al.*, 2006; Huang *et al.*, 2008; Lopez *et al.*, 1998; Gupta *et al.*, 2001; Sahu *et al.*, 2013; Cusack *et al.*, 2018; Deihimi *et al.*, 2018a), catalysts (Wang *et al.*, 2008; Jahromi and Agblevor, 2018; Ordóñez *et al.*, 2001; do Prado *et al.*, 2017; Paredes *et al.*, 2004; Yanik *et al.*, 2001; Bento *et al.*, 2016), soil amendment (Evans, 2016; Klauber *et al.*, 2011; Liu *et al.*, 2011), ceramic production, pigments and paints, steel making and slag additive.

Metal Recovery

Recovery of metals from RM has attracted many research interests due to increasing demand and value for aluminum, iron, titanium and rare earth elements such as vanadium, gallium, scandium, zirconium and lanthanides. Iron oxide is the major oxide in the RM followed by alumina, silica, titanium dioxide and rare earth elements. Therefore, diverse topics concerning extraction of valuable metals from RM have been put forward in a large number of researches (Liu and Naidu, 2014). Treatment of the RM has different metallurgical ways consisting of pyro-metallurgy, hydrometallurgy and bioleaching. Pyro-metallurgical and hydro-metallurgical treatments are the two most commonly used methods to recover valuable metals from RM (Binnemans *et al.*, 2015). Despite the researches accomplished in recovery of metals from RM, pyro-metallurgical processes have many obstacles such as high energy consumption and generation of worthless residues. In contrast, hydrometallurgical processes are more promising for the future. However, metals can be recovered from RM either by direct metallurgical methods or by combining hydrometallurgical method with a pyro-metallurgy or bioleaching. The combined bio-hydrometallurgical method is called as a green process for recovery of valuable metals from RM (Liu and Li, 2015). Among the hydrometallurgical methods of extraction, acid leaching of metals from RM is an effective way due to its potential to allow selective recovery through extraction (Pepper *et al.*, 2016). Development of convenient metallurgical processes for metal recovery from RM plays a significant role to achieving zero waste and a thorough recovery of valuable minerals inside the RM. A brief overview on basic techniques applied for valuable metals recovery including aluminum, iron, titanium and rare earth elements (REEs) from RM are propounded in the following subsections:

Iron recovery

Iron oxide in RM is typically the major constituent. The RM is considered as a low-grade iron ore containing 30%–50% iron (Jayasankar *et al.*, 2012). As the high iron content of the Bayer RM, many attempts have been carried out on iron recovery including

direct magnetic separation (Li *et al.*, 2011; Jamieson, 2006), roasting and reduction smelting processes (Liu and Li, 2015), reduction roasting by adding sodium salt (Roasting *et al.*, 2012), reductive roasting followed by magnetic separation (Li *et al.*, 2014), reduction in hydrogen atmosphere followed by magnetic separation (Samouhos *et al.*, 2017), magnetic separation after co-roasting with pyrite (Liu *et al.*, 2014), thermal plasma technology (Jayasankar *et al.*, 2012), microwave reductive roasting (Samouhos *et al.*, 2013), mineral acid leaching (Pepper *et al.*, 2016), and selective leaching of iron with oxalic acid (Yu *et al.*, 2012; Yang *et al.*, 2015, 2016). Below is a detailed investigation of the recovery of iron from RM:

Due to lower energy costs, iron recovery by direct magnetic separation from RM is more attractive than pyro-metallurgical methods. The RM was directly separated by high gradient superconducting magnetic separation system into the high and very low iron content fractions, about 56% as Fe_2O_3 and less than 4% Fe_2O_3 , respectively (Jamieson, 2006).

The iron recovery efficiency can be increased by pyro-metallurgical method or direct reduction. Pyro-metallurgy which consists thermal treatment is one of the most widely applied method to recovery of iron from RM. The amount of RM is either diminished by using a magnetic separation technique to recover iron, or declined by smelting to produce pig iron (Kumar, 1998). The pig iron was also produced by thermal plasma technology from RM. The smelting reduction of RM was performed in a 35 kW DC extended arc thermal plasma reactor. Maximum recovery of iron was reported about 71% (Jayasankar *et al.*, 2012).

Another significant iron recovery technique from RM is direct reduction roasting process. The reductants in gaseous or solid phases are essential for direct reduction. The most common reductants are carbon powder (Liu *et al.*, 2009), coal (Roasting *et al.*, 2012), low-ash coal char (Liu *et al.*, 2012), carbon (Liu *et al.*, 2009; Raspopov *et al.*, 2013) and coke (Rath *et al.*, 2013). Carbon source, the carbon-to-RM ratio, temperature, and magnetic conditions are main parameters involved in the roasting process. In this process, the RM is first mixed with carbon and then the resulting mixture is roasted at 1300°C for 110 min before quenching with water. Afterwards, the product is milled and exposed to the magnetic separation. Total content of iron in concentrated materials can reach more than 88% (Liu *et al.*, 2009).

The reduction of iron in the RM is accompanied by various chemical reactions, as illustrated by reactions (7)–(13) (Rath *et al.*, 2013):

Pyro-metallurgical processes require high energy consumption for the sintering and roasting stages and generate valueless residues (Oustadakis *et al.*, 2008). Therefore, apart from pyro-metallurgical iron recovery processes from RM, hydrometallurgical methods have widely been investigated. Various acids such as sulfuric, hydrochloric and oxalic acids have been examined for iron recovery from RM. An iron recovery efficiency of around 47% was obtained by using 8 N H_2SO_4 and a solid-to-liquid ratio of 0.05 g/ml at the leaching temperature of 100 °C for 24 h (Debadatta and Pramanik, 2013). Another study showed that a high iron recovery of more than 97% can be obtained by using 6 M H_2SO_4 and calcination at 600°C (Liu and Li, 2015). Furthermore, it was found that the 6 M H_2SO_4 solution could leach more than 97% of the iron and 64% of the aluminum in the calcined RM at 600°C (Uzun and Gülfen, 2007).

Oxalic acid leaching of RM led to the recovery of iron in the form of Fe_2O_3 with a purity of more than 98%. Experiments demonstrated that the iron was first leached out in the form of $\text{Fe}(\text{C}_2\text{O}_4)_3^{3-}$ complex in the liquor obtained by oxalic acid leaching of RM and then purified by co-precipitation, selective dissolution and re-precipitation (Yang *et al.*, 2016). In order to reduce the cost of iron recovery, Yang *et al.* (2015) first washed the RM with diluted hydrochloric acid and subsequently treated the RM using oxalic acid. As a result, an iron recovery efficiency of more than 94% was obtained. Another study evinced that the iron content of the RM could be reduced from 17.6% to less than 1% after treating it by 1 M oxalic acid solution at 75°C for 2 h. Then the solution was exposed to UV light irradiation to appear Fe(II) precipitate (Yu *et al.*, 2012).

Aluminum recovery

The remaining aluminum in the RM composition ranges from 14% to 17% (Liu and Naidu, 2014). Among the metallurgical processes of aluminum recovery, the most notable ones are sintering process (Qiu-sheng *et al.*, 2008), reduction sintering process (Li *et al.*, 2009), hydrothermal process (Zhang *et al.*, 2011), combined pyro- and hydro-metallurgical process (Piga *et al.*, 1993), reduction sintering and magnetic separation, acid leaching, and bioleaching (Wang *et al.*, 2018b; Liu and Li, 2015). Variety of organic or inorganic acids, comprising of sulfuric, citric, hydrochloric and oxalic acids, individually or as a mixture, were extensively employed to extract alumina from the RM (Pepper *et al.*, 2016; Liu and Li, 2015; Liu *et al.*, 2007). The recovery of Al from the RM depends upon the type of acid for the extraction and the origin of the waste. Among four examined inorganic acids, the highest recovery efficiencies were achieved by phosphoric acid followed by sulfuric, hydrochloric and nitric acids with similar recovery efficiency. Moreover, the dissolution of Al phases such as boehmite, gibbsite, sodalite and kaolinite played different roles in the recovery of Al from RM (Pepper *et al.*, 2016). The

rate and extent of dissolution of alumina and soda increased when calcium carbonate mixed with RM. The dried RM, with a CaO/SiO_2 ratio of approximately 2, was smelted at 1400°C and the resulting slag was leached with water at 60°C . The dissolution efficiency of Al and Na was 55% and 90%, respectively (Bruckard *et al.*, 2010). The use of a mixture of organic acids for the recovery of Al from RM has been studied. The experimental results revealed that a high Al recovery of 96% could be attained using citric acid-to-oxalic acid ratio of 2:1 at $\text{pH} = 1.5$. Furthermore, biological leaching was performed using sewage sludge bacteria and pure strains of fungi including: *Aspergillus niger*, *Penicillium notatum*, *Penicillium simplicissimum*, and *Trichoderma viride*. Acids generated by *Penicillium simplicissimum* led to a high Al recovery of 75% (Vachon *et al.*, 1994).

Alumina and ferric oxide also can be recovered from iron rich-RM by reduction sintering process. Under the favorable sintering conditions, alumina and iron oxide recovery reached 89.71% and 60.67%, respectively (Li *et al.*, 2009). Another report focused on combination of pyro- and hydrometallurgical processes to recover aluminum, iron, and titanium from RM. The RM was initially blended with coal, lime, and sodium carbonate. Then, the well-mixed materials were subjected to reduction sintering at $800\text{--}1000^\circ\text{C}$. Finally, an Al recovery of around 89% was obtained by water-leaching of the resulting fine sintered product at 65°C for 1 h (Piga *et al.*, 1993). A majority of researchers have concentrated on the recovery of aluminum under alkaline conditions. As a result of their research, three distinct processes comprising of direct second caustic leaching, smelting of RM followed by iron removal and slag leaching, and leaching of RM after a sintering stage with sodium carbonate, lime and coke have been developed. These methods ascertained that it is possible to extract aluminum up to 90% from RM by applying optional alkaline processes (Kaußen and Friedrich, 2018).

Titanium and rare earth elements (REEs) recovery

The annual enhancement in the stockpile of RM provides a noteworthy secondary resource of valuable metals and REEs. Titanium metal (Ti) is extraordinarily strong, lightweight, bio-inert and resistant to corrosion. Although Ti is expensive and has a complex processing, the advantages of using titanium outweigh its cost. Titanium dioxide or titania (TiO_2) in RM can exist in the form of anatase and rutile polymorphs or with other minerals (Oustadakis *et al.*, 2008). Pyrometallurgy- and hydrometallurgy-based methods are mainly employed for titanium retrieval from RM. Pyro-metallurgical processes typically include extracting pig iron, a soda and alumina-rich stream and a slag containing titanium, silica, lime, residual alumina and magnesium (Oustadakis *et al.*, 2008). Besides the pyro-metallurgical processes, a lot of research work has been carried out on the recovery of titanium dioxide from RM using sulfuric, phosphoric, nitric and hydrochloric acids (Pepper *et al.*, 2016). It has been found that hydrochloric acid leaching of the RM followed by sodium carbonate roasting of the leached residue significantly increases TiO_2 recovery from 36% to 76%. To achieve such an increased recovery, the leaching temperature, roasting temperature and time should be 90°C , 1150°C and 115 min, respectively (Kasliwal and Sai, 1999).

Solvent extraction is another possible technique for the recovery of titanium from RM. In this process, the use of hydrochloric acid containing bis-(2,4,4-trimethylpentyl) monothiophosphinic acid (Cyanex 302) and bis-(2,4,4-trimethylpentyl) dithiophosphinic acid (Cyanex 301) led to favorable results. One important point is that the recovery of titanium does not require an exact control of pH, and titanium is easily separated from the co-recovered iron by selective stripping (Taylor, 2007).

A great number of studies have focused upon the titanium (Ti) and scandium (Sc) recovery, with a small portion on other REEs, because titanium and scandium have some unique properties for light weight alloys. These two elements are classified as critical materials due to increasingly demand. The recovery of scandium and titanium were mostly investigated by direct acid leaching method.

It was demonstrated that the combination of sulfuric acid with hydrogen peroxide (H_2O_2) could be resulted in the enhanced retrieval of scandium and titanium from RM. Various parameters including acid concentration, leaching time, leaching temperature, and solid-to-liquid ratio were shown to be effective on the scandium and titanium recovery efficiencies. Leaching with 2.5 M H_2O_2 :2.5 M H_2SO_4 mixture at 90°C for 30 min was detected to reach the highest Sc and Ti recovery efficiencies of 68% and 91%, respectively (Alkan *et al.*, 2018).

It has been proposed that the combination of sulfation, roasting and leaching can lead to the desired REEs recovery from RM. The roasting temperature, roasting time and amount of acid play a crucial role on the recovery efficiency, as the roasting temperature of 700°C , roasting time of 1 h, and 2-day sulfuric acid leaching at room temperature give rise to the scandium recovery of 60%. Under the same conditions, more than 80% of other REEs might be extracted (Rao *et al.*, 2016b).

The recovery of other REEs such as lanthanum (La), vanadium (V), zirconium (Zr), gallium (Ga), cerium (Ce), yttrium (Y) and thorium (Th) has been investigated in several researches (Marin *et al.*, 2018; Alkan *et al.*, 2018; Rao *et al.*, 2016b, 2015; Xie *et al.*, 2014; Ujaczki *et al.*, 2017b; Lyberopulu and Paris, 1994; Mukherjee *et al.*, 1990; Zhao *et al.*, 2012). A high vanadium oxide recovery of more than 99% from RM was achieved through adsorption onto activated carbon. The process included the solubilization of vanadium, adsorption onto activated charcoal, desorption, precipitation and finally calcination (Mukherjee *et al.*, 1990). Due to increasing trends of the gallium demand in electronics industry, recovery of gallium from Bayer liquor was reviewed by Zhao *et al.* (2012). By using Kelex 100 solvent extraction system, about 80% of the gallium in Bayer liquor was extracted (Zhao *et al.*, 2012). Given the current trends for REEs demand in high-technology applications and the rapid increase in their price, it is expected that research in REEs recovery from RM will continue to grow.

Cement Binders

Cement industry is confronted with serious ecological concerns. The manufacturing Portland cement not only consumes natural resources and lots of energy, but also as one of the major industrial origin of carbon dioxide (CO_2) emission, contributes to the

global warming and the formation of acid rain. In fact, this industry emits greenhouse gases (GHGs) from two main origins: clinker production process and the consumption of energy (Dongxu *et al.*, 2000; Kumar *et al.*, 2006; Hekal *et al.*, 2013; Palaniappan *et al.*, 2013). On the other hand, the growing number of strict environmental regulations has coerced the industrial communities to decrease their polluting emissions and effluents (Palaniappan *et al.*, 2013). One of the promising methods for declining environmental issues and also achieving technological and economic benefits is the increasing utilization of industrial wastes and byproducts (Dongxu *et al.*, 2000; Kumar *et al.*, 2006; Hekal *et al.*, 2013; Palaniappan *et al.*, 2013; Kumar *et al.*, 2008; Zhu *et al.*, 2012).

The reuse of RM as an inorganic additive to Portland cement has been the subject of a number of research works since 1936 (Thakur and Sant, 1983). Various positive and negative effects have been reported on the addition of RM to cement, which means that further research in this field is needed to reach a reliable and sustainable conclusion. In the case of large-scale incorporation of RM into cement, it was reported that 2.5 million tons of RM was consumed by the cement industry between 1998 and 1999 in India (Pera *et al.*, 1997).

Researchers found that the hydration reaction of Portland cement is promoted by the addition of RM as a highly alkaline medium (Pera *et al.*, 1997). The appropriate iron oxide and alumina contents of the RM can be advantageous to the strength and setting characteristics of the cement, but the sodium is detrimental. Substitution of the sodium with calcium improves the performance of the RM as an additive.

Singh *et al.* (1996, 1997b) prepared blended cements containing gypsum, bauxite and RM. The RM was opted as a source of iron and alumina in preference to other industrial wastes owing to its low silica content, and it was realized to perform better than fly ash. By optimizing the sintering temperature and the composition of the blend it was possible to prepare cements with superior setting strengths to ordinary Portland cement, with RM replacement levels of 20%–50% by dry mass. Also, the titanium content of RM was found to be advantageous to concrete strength.

Pera *et al.* (1997) thermally treated RM at an optimized temperature of 700°C to induce appropriate pozzolanic properties to RM. They indicated that Portland cement can be substituted by as high as 25% of thermally-cured RM.

Tsakiridis *et al.* (2004) evaluated the addition of RM by 1% in the raw mix for the production of Portland cement and found that the RM can be utilized as a raw material in cement production.

Senff *et al.* (2011) utilized the RM as high as 50% cement substitution in mortar and indicated that enhancement of the RM content reduced compressive and tensile strengths. In another study, Yao *et al.* (2013) scrutinized the possibility of blending RM and by-products of coal plant. Their results proved that this blend satisfies the physico-mechanical requirements of concrete. Manfroio *et al.* (2014) investigated the characteristics of cement paste containing over 15% dry or calcined RM at temperatures of 600–900°C. They concluded that the RM can be utilized as cement substitution with proper mechanical properties for construction applications. Ribeiro *et al.* (2011) corroborated that the filling effect of RM can decline the chloride penetration in concrete. Chemical activation allows to significantly improve the RM replacement level both in cements and in concretes without a decline of their physico-mechanical properties (Pan *et al.*, 2003, 2002). The restricted replacement levels of RM can be elucidated by the fact that some crucial factors such as the structure and chemical composition of constituents, and the kind of alkali activator have not been optimized. According to Glukhovskiy (1992) and Krivenko (1985), these factors are important with respect to the formation of alkaline and alkaline-alkali earth phases which consequently induce the characteristics of the resulting cement binder.

Krivenko *et al.* (2017) prepared alkali activated cements containing high volume of RM. They used RM, blast-furnace slag, and Portland cement for the preparation of blended cements. The prepared mortar cements exhibited 28-day compressive strengths of 30–60 MPa. Furthermore, they proposed an RM replacement level of 90% by mass in concrete road application.

Kang and Kwon (2017) evaluated the efflorescence properties of RM-incorporated alkali activated slag cement. They used a varying substitution ratios of RM (0%–30%). The investigations disclosed an accelerated efflorescence owing to the enhancement of nanometer-sized capillary pores originated from the incorporation of RM in the cement matrix.

Liu *et al.* (2009) firstly recovered iron from RM using direct reduction roasting process and then prepared brick specimens with aluminosilicate residue and hydrated lime. The specimens exhibited a compressive strength of about 24 MPa.

Tang *et al.* (2018) suggested to utilize RM in partial replacement of fly ash in self-compacting concrete (SCC). They examined the effect of RM on the fresh and hardened characteristics of SCC blends. Their experiments showed that the mechanical strength of concrete promoted with the enhancement of RM content. The SCC specimens containing 50% RM exhibited the best compressive strength and elastic modulus. Their microstructural analyses revealed a slight improvement in the interfacial transition zone between aggregate and cement paste for RM-based concrete.

The utilization of RM in producing cement composite mortar blocks for applications in pavement construction has been reported by Dodoo-Arhin *et al.* (2017). They observed that an RM replacement level of 5% resulted in superior or equal performance to Portland cement as the reference mortar. The increase of RM mass fraction diminished the workability of mortar, while both the initial and final setting times were accelerated. They also proposed that the addition of appropriate super plasticizers such as melamine sulfonate and polycarboxylate ether may improve the workability of the RM-based mortars.

Hu *et al.* (2018) investigated the potential utilization of RM as a raw material for geopolymer production. They used RM and three types of fly ash to prepare geopolymers. The raw materials were activated using appropriate activators (different concentrations of sodium hydroxide) and cured at both ambient and elevated temperatures. The geopolymers prepared from the contribution of RM and class C fly ash exhibited a compressive strength of around 15 MPa under ambient temperature curing at a low alkali activator concentration. As an overall conclusion, it was found that the high alkalinity of RM contributed to geopolymerization.

In another research, [Li et al. \(2019\)](#) utilized RM to prepared RM-based geopolymer. They suggested a novel activation method for the RM. Their results indicated that mechanical activation can effectively improve the reactivity of the RM. The addition of 14% sodium silicate to the prepared binder, the 28-day unconfined compressive strength reached 12.75 MPa.

[Ye et al. \(2016\)](#) revealed that alkaline heat treatment could be used to tailor the mechanical strength of RM-based geopolymer. However, this type of treatment method is expensive, making the industrialization very challenging ([Pacheco-Torgal et al., 2012](#)).

Adsorption

Since removal of organics and inorganics pollutants from aqueous media is necessary for health and environmental protection, conventional methods such as reduction, precipitation, adsorption, oxidation, membrane filtration and ion exchange are commonly used. However, among them the adsorption process is the most suitable method because of high efficiency, flexibility in design and operation, and low operational cost ([Burakov et al., 2018](#); [Li et al., 2017a](#)). Industrial solid wastes have been applied as effective adsorbents due to the easy availability and economic feasibility. Among them, RM presents an adsorption capacity for removing heavy metals from wastewater ([Burakov et al., 2018](#)). Moreover, the RM has been found to remove fluoride, arsenate, phosphate, nitrate, hexavalent chromium, copper, cadmium, lead and dyes from aqueous solution ([Li et al., 2006](#); [Bhatnagar et al., 2011](#)). Also, the RM adsorption efficiency has been compared with other low-cost adsorbents in the literature ([Liu et al., 2011](#); [Narayanan and Vetha, 2017](#); [Hu et al., 2018](#); [De Gisi et al., 2016](#)). Several activation methods have been suggested to increase the adsorption properties of RM such as acid treatment, heat treatments and mixing the RM with other materials ([Pinto et al., 2018](#)). The resulting activated RM as an inexpensive adsorbent was found to efficiently remove polluting species from aqueous solutions ([Deihimi et al., 2018b](#)). **Table 4** provides a summary of adsorption experiments and their corresponding results using the RM as adsorbent. As it can be seen, the RM, modified RM, and the adsorbents synthesized from the RM exhibit good adsorption capacities for a wide range of aqueous pollutants.

Soil Amendment

In spite of the fact that RM is often contaminated with heavy metals, its application in environmental remediation has extensively been investigated. However, the RM could be an efficient soil amendment due to its fixation of heavy metals. The leaching of metals, especially heavy metals, into the environment leads to soil pollution and contamination. The heavy metals are invariable and they are not as degradable as organic pollutants in the soil. The RM can easily adsorb different metal ions and it has a significant effect in removing heavy metals from contaminated soil ([Klauber et al., 2011](#); [Liu et al., 2011](#); [Ciccu et al., 2003](#); [Hua et al., 2017](#)).

According to [Hua et al. \(2017\)](#), a preliminary decision tree scheme (see **Fig. 11**) can be suggested to evaluate the suitability of RM as soil amendment agent. According to **Fig. 11**, the suitability of the RM for soil amendment depends on soil pH, soil electrical conductivity, and total potentially toxic elements (PTEs) of RM.

The chemical and biological effects of in-situ fixation of metals in soil using the RM were investigated by [Lombi et al. \(2002a,b\)](#). They examined efficiency of RM to stabilize heavy metals in two types of soils, soils polluted by industrial activities and sewage sludge. In both soils, using red mud resulted in low concentrations of metals in metal fluxes and the soil pore water. Due to increasing soil pH, the RM amendment not only shifted metals from the exchangeable to the Fe-oxide fraction, but also reduced acid extractability of metals ([Lombi et al., 2002a](#)). Moreover, three soil amendments (RM, beringite and lime) examined to two soils contaminated by heavy metals. All three soil amendments reduced phytotoxicity of heavy metals and the metal concentrations in plants as well as increased plant yields and soil microbial biomass ([Tor and Cengeloglu, 2006](#)). The neutralized RM (pH < 8) has the capability to decrease phosphate leaching into ground and surface waters due to the high concentration of iron and aluminum oxides ([Summers et al., 1996](#)).

In another study, the RM mixed with the sandy soil ranged between 0 and 50%. The results demonstrated that the RM applied at 5% had positive effects on the degraded acidic sandy soil, remarkably by increasing soil pH, improving water holding capacity and soil texture ([Ujaczki et al., 2016a](#)).

Since the mobility of metals is closely related to pH, the RM amendment of contaminated soil can enhance metal release from the amended soil. Moreover, the RM-amended soil can result in benefits for ecosystems in decreasing the mobility of potentially toxic elements to transfer to the environment ([Hua et al., 2017](#)). The use of RM for soil amendment would be an effective way to decrease the current storage.

Catalysis

The utilization of industrial solid wastes containing catalytically-active metals such as Ni, Fe, V etc., as an alternative to commercial catalysts can assist decrease the cost related to the use of catalyst. The RM which is majorly a combination of inorganic oxides of Fe, Al, Ti and a few amounts of Si, Na and Ca is a potential alternative catalyst at the commercial scale ([Pirkanniemi and Sillanpa, 2002](#)).

The simultaneous presence of various metal oxides in the RM composition makes it less susceptible to catalyst poisons like sulfur, and hence it is able to retain its catalytic activity over a relatively long period of time ([Sushil and Batra, 2008](#)). In addition,

Table 4 Summary of the different methods and techniques utilized to red mud as an adsorbent

Adsorbate	Methods and techniques	Maximum adsorption capacity	Ref.
Fluoride	Granular RM in batch adsorption systems	0.851 mg/g	(Tor <i>et al.</i> , 2009)
Fluoride	1 – Untreated RM	1 – 13.46 mg/g	(Wei <i>et al.</i> , 2009)
	2 – AlCl ₃ -modified RM	2 – 68.07 mg/g	
	3 – Thermally-treated RM at 200°C	3 – 91.28 mg/g	
Fluoride	Fe-Al-La trimetal hydroxide adsorbent from RM	74.07 mg/g	(Li <i>et al.</i> , 2017c)
Fluoride	HCl-activated RM	Maximum removal of 82% at pH 5.5	(Cengeloglu, 2002)
Phosphate	HCl-treated RM at pH 5.5 and 40°C	0.58 mg/g	(Huang <i>et al.</i> , 2008)
Phosphate	1 – Heat-activated RM (700 °C for 2 h)	1 – 155.2 mg/g	(Chang-jun <i>et al.</i> , 2007)
	2 – Acid-modified RM (80°C with 0.25 M HCl for 2 h)	2 – 202.9 mg/g	
Phosphate	Acid/heat-treated RM (0.25 M HCl for 2 h, 700°C for 2 h)	155 mg/l (99% phosphate removal)	(Li <i>et al.</i> , 2006)
Phosphate	Acid-activated RM (1 M HCl for 2 h)	205.13 mg/g	(Prajapati <i>et al.</i> , 2016)
Phosphate	Gypsum and seawater-treated RM	0.345–2.73 mg/g	(Cusack <i>et al.</i> , 2018)
Nitrate	1 – RM	1 – 1.859 mmol/g	(Cengeloglu <i>et al.</i> , 2006)
	2 – HCl-activated RM	2 – 5.858 mmol/g	
Arsenic	RM-modified rice straw biochar	5923 µg/g	(Wu <i>et al.</i> , 2017)
Arsenic: As(III) and As(V)	Heat/acid-treated RM:		(Altundog <i>et al.</i> , 2002)
	Heat treatment at 200, 400, 600 and 800°C for 4 h	As(III): 11.80 µmol/g	
	Acid-treatment with 0.25–2.0 M HCl at 25, 40, 55 and 70°C for 2 h	As(V): 12.57 µmol/g	
Arsenic (V)	1 – Chemically-modified RM (Bauxsol)	1 – 1.64–3.32 mg/g	(Genç-Fuhrman, 2005)
	2 – Activated Bauxsol (AB)-coated sand	2 – 2.14 mg/g	
Arsenic (III)	RM coated with Fe ₂ O ₃	21.85 mg/g	(Venkatesan and Narayanan, 2018)
Cadmium	Granular RM at 20, 30, and 40°C in batch experiments	38.2 mg/g at 20°C 43.4 mg/g at 30°C and 52.1 mg/g at 40°C	(Zhu <i>et al.</i> , 2007)
Cadmium	RM	1.16 × 10 ⁻⁴ mol/g	(Gupta and Sharma, 2002)
Cadmium	RM in the presence of 0.01 M NaNO ₃	68 mg/g	(Vaclavikova <i>et al.</i> , 2005)
Chromium and lead	Hydrogen peroxide-treated RM	Chromium: 35.66 mg/g Lead: 64.79 mg/g	(Gupta <i>et al.</i> , 2001)
Lead	RM	18.87 mg/g	(Mobasherpour <i>et al.</i> , 2014)
Lead(II)	0.5 M HCl-treated RM coated with iron oxide	27.02 mg/g	(Narayanan and Vetha, 2017)
Nickel(II)	Calcined and ground RM (63–125 µm)	13.69 mg/g	(Taylor and Hannachi, 2010)
Zinc	RM	2.22 × 10 ⁴ mol/g	(Gupta and Sharma, 2002)
Zinc	RM in the presence of 0.01 M NaNO ₃	133 mg/g	(Vaclavikova <i>et al.</i> , 2005)
Methylene Blue	6 M HCl-activated RM at 90 °C for 2 h	274 mg/g	(Hu <i>et al.</i> , 2018)
Methylene Blue	hydrogen peroxide-treated RM at room temperature for 24 h	(4.35–5.23) × 10 ⁻⁵ mol/g	(Gupta <i>et al.</i> , 2004)
Fast Green		(7.25–9.35) × 10 ⁻⁶ mol/g	
Rhodamine B		(1.01–1.16) × 10 ⁻⁵ mol/g	
Congo Red	RM boiled in 20 wt% HCl for 20 min	7.08 mg/g	(Tor and Cengeloglu, 2006)

the coexistence of these metal oxides might ameliorate the synergistic catalytic influence between transition metals (Guimaraes *et al.*, 2009; Xu and Wang, 2012).

According to Fig. 12, the RM has successfully applied as catalyst in various reaction areas including hydrodechlorination and dechlorination, hydrogenation, oxidation, exhaust gas clean-up, and miscellaneous reactions.

Oxidation reactions

It has been extensively accepted that catalytic oxidation is a very interesting method for removal of volatile organic compounds (VOCs), which induce intense environmental detriments. In this field of research, the noble and transition metals have been widely employed to eliminate VOCs, but with various restrictions (Hua *et al.*, 2017; Shim and Kim, 2010; Kamal *et al.*, 2016; Zhang *et al.*, 2016). The co-presence of metal oxides in RM sparks the idea of using the RM as an alternative catalyst for replacing the commercial noble metal and transition metal oxides in catalytic-related applications. Proper treatments can be applied to prepare RM-based catalysts. For instance, loading of Pt on the air-thermally treated RM was very efficient for the removal of VOCs (Kim *et al.*, 2015).

Fig. 11 The proposed decision tree scheme for evaluating the utilization of red mud as soil amendment agent.

Fig. 12 Catalytic application of red mud in different reaction areas.

As the RM contains significant amounts of Fe_2O_3 and Al_2O_3 , it can exhibit a CO_2 selective behavior in the toluene oxidation reaction. The RM activity can be associated directly with the amount of iron. It has been observed that the chemical reaction specific rate (in terms of gram of Fe_2O_3) in the presence of RM is similar to that monitored in the presence of analytical grade Fe_2O_3 (Lamonier *et al.*, 2005).

Methane oxidation is another conducted experimental research. Paredes *et al.* (2004) prepared iron-based catalysts from RM by dissolution–precipitation techniques, followed by calcination in air. The RM was treated using a combination of hydrochloric and ortho-phosphoric acids. The activity and stability of the prepared catalysts for the catalytic combustion of methane was found to be comparable to that of hematite and a Cu–Cr–Ti commercial catalyst.

Oliveira *et al.* (2014) proved that biphasic oxidation reactions of organic pollutants with H_2O_2 were improved by amphiphilic catalysts from RM and carbon nanostructures.

Shim *et al.* (2018) evaluated the RM as a potential catalyst support for the complete oxidation of toxic organic compounds. They pretreated the RM using calcination and HCl. Then, the acid-treated RM was loaded with various amounts of Pd. The HCl-treated RM exhibited a better catalytic activity for complete oxidation of benzene.

Huab *et al.* (2016) prepared CuO/activated-RM with high specific surface area and suitable porosity by a series of dissolution-precipitation techniques. The resultant catalyst showed a high catalytic CO oxidation.

Hydrogenation reactions

The catalytic utilization of RM was first reported by Pratt and Christoverson (1982) for hydrogenation of naphthalene. They proposed acid dissolution and re-precipitation method for the activation of the RM. According to this method, the RM was

dissolved in HCl to obtain a metal chloride leachate. The re-precipitation was then performed by the addition of ammonia. It was found that untreated RM exhibited a naphthalene conversion efficiency of 3.55% while the treated RM possessed a conversion efficiency of 58%. Eamsiri *et al.* (1992) activated the RM by the Pratt and Christoverson method and used the activated RM for hydrogenation of phenanthrene, naphthalene, and pyrene. They observed a considerable promotion in the hydrogenation of the tested compounds. However, activation did not result in notable enhancements in overall yields of liquids and the activated RM was considerably less active than a commercial Ni–Mo–S catalyst.

In another research, Llano *et al.* (1994) used RM and activated RM for the hydrogenation of an anthracene oil. They applied the Pratt and Christoverson method to activate the RM. The RM exhibited a remarkable catalytic activity, which was meliorated by the activation. However, both RM and activated RM showed less catalytic activity than a commercial Ni–Mo/ γ -alumina hydro-treating catalyst.

Alvarez *et al.* (1995) showed that sulfided RM exhibited activity for the hydrogenation of a light fraction of an anthracene oil. They found that catalytic activity of the catalyst decreased with reaction time, due to the decline in surface area and superficial iron. In another research work (Alvarez *et al.*, 1998), they activated the sulfided RM by Pratt and Christoverson and divulged that the catalytic activity loss of the catalyst was slower than that of untreated sulfide RM. In a later study, the same authors (Alvarez *et al.*, 1999) improved the catalytic hydrogenation performance of RM by proposing a different activation method. They dissolved the RM in a mixture of aqueous HCl and H_3PO_4 and then obtained a precipitate by the addition of aqueous ammonia until pH value of 8. The precipitate was rinsed, dried, and calcined to obtain catalyst. After sulfidation, the activity and life of the prepared catalyst was examined for the hydrogenation of a light anthracene oil. The results confirmed a slightly better activity and a noticeably active life.

Hydrodechlorination and dechlorination reactions

Catalytic dechlorination and hydrodechlorination reactions are efficacious and ecofriendly methods for the decomposition of chlorinated organic compounds. A typical hydrodechlorination reaction includes the reaction between organic molecule containing C–Cl bond and hydrogen:

Several studies have been reported on the catalytic application of RM in hydrodechlorination and dechlorination reactions. Ordoñez *et al.* (1999, 2001a) comprehensively investigated the utilization of RM as a catalyst for hydrodechlorination of tetrachloroethylene. They evaluated the catalytic activity of sulfided RM and RM based-sulfided catalysts and found that the sulfided RM presented a better activity. But the catalyst suffered from a low stability at reaction conditions, because of poisoning by HCl (Ordoñez *et al.*, 1999).

The same authors continued their investigations to overcome low stability drawback. They treated the RM using dissolution-precipitation-calcination method. In this method, the RM was first dissolved in a binary acid mixture ($HCl + H_3PO_4$). The resulting solution was then precipitated by adding ammonia. Finally, the precipitate was calcined at 500°C to obtain the catalyst. The prepared catalyst exhibited a better catalytic activity and resistance to deactivation compared to untreated RM (Ordoñez *et al.*, 2001b). Then, they measured the conversion in terms of reaction time in the presence/absence of carbon sulfide in the feed and discovered a notorious enhancement in the catalyst life in the presence of carbon sulfide (Ordoñez *et al.*, 2001b).

Halasz *et al.* (2005) first calcined the RM and then used it for catalytic hydrodechlorination of 1,2-dichloroethane, 1,1,2-trichloroethane, 1,1,2,2-tetrachloroethane, trichloroethene and tetrachloroethene. They compared the catalytic activity of the calcined RM with other iron-based catalysts, such as Fe_2O_3 , mixed Fe_2O_3/Al_2O_3 , and modified zeolite (Fe-ZSM5). The catalytic conversion of the mentioned compounds over calcined RM is comparable to that obtained for synthetic catalysts. Furthermore, the reactions occurring over RM caused a decline in alkalinity of RM making it more appropriate for disposal.

Yanik *et al.* (2001a,b) employed RM as a dechlorination catalyst for the disintegration of waste plastics and poly (vinyl chloride) (PVC) containing PVC/PP, PVC/PE, and PVC/PS into fuel oil. They found that the RM was showed a positive effect on the fixation of formed HCl gas. The RM exhibited a very efficient sorption of both inorganic and organic chlorine compounds.

Exhaust gas purification

The RM has already been studied for the catalytic removal or destruction of certain air pollutants. Among these studies are the following: recovery of sulfur from sulfurous waste gases (Khalafalla and Haas, 1972), catalytic combustion of methane (Khalafalla and Haas, 1972), selective catalytic reduction of NO_x (Lamonier *et al.*, 1995; Hosoda *et al.*, 1995), elimination of VOCs, removal of HCl from exhaust gases, dioxins and CO (Junji *et al.*, 2002), hot gas clean-up of coke oven gases and gasification products (Furimsky and Yumura, 1986).

The RMs from different sources have been employed as catalysts for reduction of SO_2 in the presence of CO. It was found that the RM wastes having high Al and Fe content exhibited good catalytic activity (Khalafalla and Haas, 1972).

Lamonier *et al.* (1995) investigated RM and Cu-impregnated RM for the selective catalytic reduction of NO_x . Paredes *et al.* (2004) studied catalytic activity and stability of RM and activated RM in the catalytic combustion of methane. Their experimental results signified that the RM exhibited the least activity, while activated RM presented the best performance for the catalytic combustion of methane both in terms of activity and resistance to deactivation. The inferior activity of RM was ascribed to the presence of catalytically inert constituents in the chemical structure of RM such as rutile, gibbsite, and goethite.

Li *et al.* (2017b) in their research found that the RM could exhibit an excellent activity in the selective catalytic reduction of NO_x . They proposed grinding/acid-alkali neutralization technique to utilize the RM waste as iron-based catalyst. The resulting catalyst presented a NO conversion of more than 90% above 400°C in the presence of SO_2 and H_2O . The result is even better than that of a commercial V-W-Ti catalyst. In another study in the same year, Wu *et al.* (2018) prepared low-cost RM-based catalyst and tested it in the ammonia-selective catalytic reduction of NO_x . They concluded that the RM was a potential material for denitration catalyst. Their results demonstrated that the doping of Ce significantly increased the NO_x conversion as much as 88%.

Miscellaneous reactions

The possibility of using the RM as a catalyst in other reactions has also been reported in the literature. Despite previously reported results, this sub-section deals with recent research.

Feng *et al.* (2016) used RM powders as catalysts for persulfate activation with sulfadiazine as the target pollutant. Their results indicated that the RM powder had a scavenger impact on the rate of sulfadiazine decomposition. They found that under the conditions of 2 g/L RM powder and 1.75 mM persulfate, the sulfadiazine could be completely decomposed.

Senthil *et al.* (2016) examined the catalytic performance of activated RM in biodiesel production from Mahua oil. From their findings, it was obvious that the use of RM as a catalyst not only enhances fuel quality, but also decreases adverse impacts on the environment.

Lee *et al.* (2016) developed ZrO_2 -impregnated RM catalysts for catalytic steam cracking of vacuum residue. They observed that the impregnation of RM with 3 wt% ZrO_2 resulted in the best catalytic performance, provided that the reaction was carried out at 470°C for 2 h under superheated steam atmosphere.

Yang *et al.* (2018) studied the catalytic mechanism of the RM on the sewage sludge pyrolysis. The RM could diminish the average activation energy of sewage sludge pyrolysis by around 20.1 kJ/mol. The char produced from RM-catalyzed pyrolysis of sewage sludge featured magnetic characteristic, which has different applications. The overall results revealed desirable catalytic activity of the RM in the pyrolysis of sewage sludge.

Jahromi and Agblevor (2018) in their research work, prepared RM supported nickel (Ni) catalysts at various concentrations of Ni. They used these catalysts to hydrodeoxygenate pinyon-juniper catalytic pyrolysis oil. According to their results, increasing the Ni concentration promoted the performance of the catalyst.

Noble metals (Pt, Pd, Ru)-supported RM catalysts were investigated for alkane synthesis from carboxylic acids and furans by Castille *et al.* (2019). They reported a maximum alkane selectivity of 100%, 87%, and 56% over Pt-, Pd-, and Ru-RM, respectively.

Other Applications

In addition to the main uses mentioned above, the RM has also been studied in other applications. Some of the RM-related patents are attributed to the application of RM in steel making and slag additives. The RM is considered as one of possible supplements utilized as a source of Al, Si, and Ca to improve the setting, separation, and quality characteristics of the slag (Klauber *et al.*, 2009).

Generation of ceramic products such as double-layer glass-ceramic tile (Yang *et al.*, 2009), glass ceramic foam materials (Guo *et al.*, 2014), roof tile/brick (Scribot *et al.*, 2018; Liu *et al.*, 2017), and lightweight ceramic floor (Wang *et al.*, 2018a) are from other areas of RM application. The microstructural and mechanical characteristics disclosed that the production of double-layer glass-ceramic tiles from the RM may be an attractive approach for converting the RM into building materials (Yang *et al.*, 2009). The low bulk density glass ceramic foams can be produced by blending RM, fly ash, and CaCO_3 as foaming agent at low sintering temperature (Guo *et al.*, 2014). By replacing natural clay with 30 wt% of low sodium hydroxide-containing RM and applying calcination temperatures of above 950°C, ceramic tiles with acceptable properties can be allowed (Scribot *et al.*, 2018). The ceramic bricks with excellent water permeability and much decreased pH and conductivity could be fabricated by mixing appropriate proportions of RM, water, and silicon dioxide. After homogenization, a 5 MPa press was exerted on the obtained blend. Thereafter, sintering was performed at temperatures higher than 1100°C (Liu *et al.*, 2017). The RM in combination with kaolin through a $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24}$ -catalyzed pathway can result in the preparation of low-cost ceramic floor tiles. It was found that the catalytic route promoted the growth of mullite crystals. This promotion is due to the unique properties of mullite such as its low thermal conductivity and low thermal expansion as well as its excellent fracture toughness (Wang *et al.*, 2018a).

The high iron content in RM made it an appropriate component in pigments and paints. A variety of brown-red shades produced by the RM (Klauber *et al.*, 2011; Rai *et al.*, 2012; Mishra and Gostu, 2017). Sintering the RM at 1300°C makes it suitable alternative for the hematite pigment (Carneiro *et al.*, 2018b). Combining the RM with electroplating sludge in different proportions, following by calcination at 1200°C could result in black and brown pigments with appropriate coloring strength and thermal stability (Carneiro *et al.*, 2018a).

The use of RM in the preparation of composite RM/polyaluminum chloride coagulant is expected to be cost-effective for the efficient removal of phosphate from aqua medium (Ni *et al.*, 2015). The RM can also be used as Al source for the fabrication of magnetic zeolite. In a recent study (Belviso *et al.*, 2018), wool ball-shaped zeolite was synthesized using the RM and colloidal silica. The prepared zeolite can be considered for wastewater treatment. The RM can even be used for neutron shielding application. For this purpose, the RM was first treated with boric acid and then mixed with polyester resin (Guru *et al.*, 2019).

Fig. 13 Current barriers in the way of the use of red mud.

Challenges and Future Perspective

The worldwide stockpiles of RM on the planet are estimated at more than 2.7 billion tons. Annually, 120–150 million tons are added to this amount. The RM has not been distributed uncontrollably in the world, but is prevalently distributed in discrete locations almost controlled or under strict rules. In spite of the long-standing knowledge of the disadvantages of RM accumulation as well as the suggestion of a wide variety of solutions for the utilization of RM, the controlled waste disposal is still preferable to other methods, considering social, environmental, and economic conditions. The best way to solve RM disposal problems is to develop economic exploitation technologies that can process a huge amount of RM. The current barriers that need to be overcome are presented in Fig. 13.

An impressive impact on the amount of stored RM requires the development of technologies and recycling/recovery/reuse methods that can process large amounts of RM. The performance of the waste in each particular application must be able to compete with the existing options in terms of quality and cost. Also, metals and metal oxides extracted (as micro/nano form), composite products, adsorbents, catalysts, and other products should have physical, chemical, mechanical, and thermal properties comparable to existing alternatives. Economic feasibility and life cycle assessment should be performed for any process in order to provide an appropriate economic vision for industries and investors. In these assessments, the energy consumption and the downstream processing economy should also be taken into account. As far as possible, processes may be designed in such a way that their byproducts are reusable to make the process economy more desirable. For each specific application and utilization method, it should be explained that related risks are less than those dealt with controlled storage. These risks comprise environmental, public health, safety, and economic issues. Specifically, soda removal, alkalinity reduction, stabilization of heavy metals and rare earth metals should be considered further.

Conclusions

Different aspects of red mud including the production process, characterization, environmental effects, utilization methods, and challenges are elucidated in the current review study. The characterization section comprehensively explains chemical and mineralogical compositions, radioactivity, particle size distribution, and morphology of the red mud by giving an example from Iran Alumina Company waste. The main focus of this study is on the various methods of utilizing the red mud. The major applications of the red mud are presented in areas of metal recovery (iron, aluminum, titanium, and rare earth elements), cement binders, adsorption, soil amendment, and catalysis. Also, the other applications of the red mud are briefly mentioned. The valuable metals recovery from the red mud is mainly based on hydrometallurgical methods and techniques. Almost all recovery methods remain on a laboratory scale without any appropriate analysis to execute lab-scale into pilot or industrial scale. The physico-mechanical and durability characteristics of red mud indicate that it can be utilized in the production of construction and building materials, but in small proportions. In addition, red mud in some origins contains trace radioactive elements, necessitating further research to study radiation conditions. In adsorption application, the red mud appears to need to be activated to exhibit suitable adsorption capacities for a wide range of aqua pollutants. The application of red mud as soil amendment agent can be a promising option for the large volume utilization of red mud. However, this application depends on soil pH and the level of toxic elements both in soil and in red mud. The catalytic performance of red mud can be comparable with available commercial catalysts, if some appropriate modification/activation techniques are applied to improve the specific surface area and synergistic effect. The utilization of red mud in other fields such as ceramic products, pigment, coagulant, etc., requires additional research work.

Glossary

Biocomposites They are a composite material formed by a matrix (resin) and a reinforcement of natural fibers.

Bulk molding compound (BMC) Polyester resin/glass fiber premix, for injection or transfer molding, also known as dough molding compound (DMC).

Carbon fiber Reinforcing fiber known for its light weight, high strength, and high stiffness.

Composite A material made up of resin and reinforcement (usually fiber).

Fiber-reinforced polymer (FRP) A general term for composite materials or parts that consist of a resin matrix that contains reinforcing fibers such as glass or fiber and have greater strength or stiffness than the resin. FRP is most often used to denote glass fiber-reinforced polymer.

Fiber A unit of matter of relatively short length, characterized by a high ratio of length to thickness or diameter.

Glass fiber Reinforcing fiber made by drawing molten glass through bushings. The predominant reinforcement for polymer composites, it is known for its good strength, processability, and low cost.

Impregnation Saturation of reinforcement with liquid resin.

Polymer A long-chain molecule, consisting of many repeat units.

Recyclates The raw material collected, taken to, and processed in a waste recycling plant or materials recovery

facility that will be used in the manufacturing of new materials.

Recycling The process of converting waste materials into new materials, products and objects.

Reinforcement Key element added to resin (matrix) to provide the required properties; ranges from short fibers and continuous fibers through complex textile forms.

Resin Polymer with indefinite and often high molecular weight and a softening or melting range that exhibits a tendency to flow when subjected to stress. As composite matrices, resins bind together reinforcement fibers.

Scanning electron microscope (SEM) A type of electron microscope that is used to produce enlarged images of a sample by scanning the surface with a focused beam of electrons, like reinforced CFRP samples. When the samples are placed under the microscope, the electrons mix with the constituent atoms within the composite sample. This will produce different signals that contain information about the surface topography and composition of the sample.

Sheet molding compound (SMC) A flat prepreg material, comprising thickened resin, glass fiber, and fillers, covered on both sides with polyethylene or nylon film, ready for press-molding.

Thermoplastic A plastic that softens each time it is heated.

Thermoset A plastic that flows and then sets permanently on first heating, as a result of setting up a three-dimensional cross-linked molecular structure, and subsequently will not soften or dissolve.

Introduction and Background

Current trends in the use of composites have developed into more applications in various sectors. In the offshore industry, there are some challenges with the standards on the use of offshore composites, particularly as structural members. However, composites are lightweight and can be used on other areas of the offshore sector. Some research into the use of recycled composites, like other composites, show that they are good reinforcement materials, depending on the purpose of application (Gibson, 2003; Wei *et al.*, 2018; Hornsby and Bream, 2001). Boats and some leisure ships made of composites can also be recycled (Sponberg, 1999). Studies have also been carried out on the life cycle for both FRP and glass reinforced polymer (GRP) composites (ISO, 2006; Song *et al.*, 2009; Bachmann *et al.*, 2017). Fig. 1 shows the offshore developments with different offshore structures showing the need for composites. As the offshore explorations go deeper into deep waters, more lengths of risers are required which also adds on the weight of the offshore platforms. Composites can be harnessed to reduce the weight as well as enable the technologies in these offshore operations. Composites have also been used to lighten the weight of automobiles and building products commercially, such as by ELG Carbon Fiber (ELG Carbon Fibre, 2016, 2017; Gehr, 2018) and Filon (Job *et al.*, 2016). Carbon fiber can be recovered, as shown in Fig. 2, by ELG Carbon Fiber. Recycled composites have also been used in fences from recycled carpets as structurally stable and fit for use (Sotayo *et al.*, 2015, 2016, 2018, 2019). These can also be deployed on offshore applications for hand rails, guard rails and safety fences in structures where the use of composites are permitted.

Fig. 1 History of offshore deep waters, showing the offshore structures and their water depths.

Fig. 2 Carbon fiber reclamation. *Source:* ELG Carbon Fiber, 2016. Reproduced from: ELG Carbon Fibre Recycled carbon fiber as an enabler for cost effective lightweight structures, Global Automotive Lightweight Materials (GALM), Detroit, 2016 ELG Carbon Fiber Ltd. Detroit Available at: http://www.elgcf.com/assets/documents/GALM_US_2016.pdf.

Due to the growing demand for more sustainable materials, there has been a global increase in the application of composites in the offshore industry. This includes composites for composite risers (Amaechi *et al.*, 2019a; Amaechi and Ye, 2017; Wang *et al.*, 2011a,b), composite tubes (Sparks *et al.*, 1992; Bhudolia *et al.*, 2015; Wang *et al.*, 2011a,b), submarine hoses (Amaechi *et al.*, 2019b), floating hoses, underwater vehicles, remotely operated vehicles, naval ships and submarines (Mouritz *et al.*, 2001), submersibles (Odijie, 2015; Odijie *et al.*, 2017a,b), SPARS (Amaechi *et al.*, 2019d) and floating production storage and offloadings (FPSOs). This trend for the demand of carbon material composites has also been observed in other industries. This includes the automobile industry, and the renewable energy (Doyle and Aggidis, 2019; Zhang *et al.*, 2019) and aerospace industry (Shi, 1996; Yang *et al.*, 2012).

ELG Carbon Fiber was the world's first commercial carbon fiber-recycler. They can take dry fiber, prepreg, and cured laminate waste. The waste is converted into the Carbisio range of products including chopped and milled fiber, oversized tow and nonwoven mats. Other products using recycled carbon fiber, including injection molding compounds, are under development. For glass fibers, there are presently the following options: In-house recycling, cement kiln, energy recovery, and landfills. For the in-house recycling, there may be ways you can recycle some of your GRP waste in-house, particularly if you use a spray-up or casting process. Grinding to fine filler is a proven route but is difficult to achieve economically. Ecowolf (Florida, USA) provides equipment for incorporating GRP regrind in spray-up processes. Conenor (Finland) provides advice/R&D services for multilayer extrusion that can incorporate GRP regrind. For the cement kiln (recycling/recovery), it involves mixing the shredded composite parts/offcuts with other waste to feed into cement kilns. Organic resin is burnt for energy; inorganic components become feedstock for cement. Carbon fibre reinforced polymer (CFRP) can also be treated this way but recycling is preferable. Agecko in UK and Neocomp in Germany (formerly operated by Zajons) promote this process specifically for the composites industry. For energy recovery, GRP wastes are sent for energy recovery, like to Viridor in Oxford, UK. The glass and filler will go to ash, but in some cases the bottom ash from incinerators is recycled rather than landfilled. Sometimes, the incinerator bottom ash will be recycled (as aggregate or in building products) or landfilled, and the waste can be exported for incineration overseas. The most common is the use of landfills as most GRP waste still goes to landfills.

The global demand for carbon fiber is estimated to greater than double to be between 150,000 t and 180,000 t by 2020. With the manufacturing techniques used today, there is approximately 30% of the overall demand for carbon fiber becoming waste both during the conversion phase and component-manufacturing phase of the recyclates. The remaining fiber is added into the finished parts, which will be disposed of later at the end-of-life (EOL). With the increase in the application of CFRP composites in components with shorter service lives, the EOL will range between 2 and 40 years, depending on the frequency of its usage (ELG Carbon Fibre, 2017).

The market drivers that determine the best disposal solutions of wastes from FRP composites are the market forces of demand and supply, the increasing cost of landfills, the increase in awareness on circular economy thinking, the markets for recycled products, government policies and legislations on recycled FRP composites. However, the most important driver on commercial viability of recycled FRP composites is the breaching of new markets (Brown *et al.*, 2018). With the increase in more composite recyclates, there is also an effect on the existing composite manufacturers, and their sources of raw materials. Currently, automobile manufacturers like BMW and VW (Volkswagen) are also researching on increasing the use of composites on their cars and also using recycled composites and biocomposites (Das *et al.*, 2016; Bharath and Basavarajappa, 2016; Mohanty *et al.*, 2018). This will also increase the economic viability of recycled FRP composites in the automobile industry. There is need to create more circular recycling on FRP composites, create higher value recycling routes to explore other areas of the market, and increase more economic exchanges and businesses both within the composites industry and with other industries such as the mainstream aviation industry, automobile industry, and construction industry.

There are four main drivers that influence the supply chain of recycling carbon fibers. They are the affordability, security, legislative policies, and environmental responsibility. The economic conversion of both the raw wastes from manufacturing and EOL components into different recycled carbon fiber shapes, forms, and component designs is very important. This material product can then be used technically for different applications, making these lightweight carbon fiber composites less expensive. With respect to the security of the supply chain, the application of recycled carbon fibers controls any supply side capacity risk by bringing in high tonnes of carbon fiber from existing production capacity, thus buffering it up. Legislation plays a very great role, as these policies are what guides the manufacturers and the end-users about the product and its circulation in the market. The need for environmental responsibility cannot be overemphasized. In the automotive industry, EU legislation requires 85% of a vehicle to be recyclable. Carbon fiber waste can be recovered and converted to new products using less than 10% off the energy required to produce the original carbon fiber, fulfilling legislative and sustainability targets (ELG Carbon Fibre, 2017).

Carbon Fiber and Glass Fiber Composites

Carbon fiber has been of high value in the composites market and can be also applied in the offshore industry. Currently, there are more carbon fiber-recycling companies that in operation and also thriving commercially. They include ELG Carbon Fiber, Filon, etc., as shown in Tables 1–3. Carbon fibers are composed of at least 92% carbon and most commonly have a diameter in the range 5–10 μm . They are polymers with a structure that is almost completely graphitic. This graphitic form of carbon fiber is a pure form of carbon in which the atoms are arranged in big sheets of hexagonal rings. The structure provides very high levels of stiffness and strength. Technically, carbon fibers have been produced and improved for many decades because of their excellent mechanical, thermal, and electrical properties, often exploited as carbon fiber composites for highly valuable applications in sectors including

Table 1 Current commercial composites recycling services for fiber-reinforced polymers GFRP and CFRP

<i>Company/location</i>	<i>Processes/capacity</i>	<i>Materials recycled</i>	<i>Recyclate market</i>	<i>Reference website</i>
ELG Carbon Fiber, (Formerly Milled Carbon), West Midlands, UK	Pyrolysis process, 2000 t/year recovered carbon fiber output	Dry carbon fiber waste, carbon fiber prepreg waste, carbon fiber laminates	Chopped/milled/pelletized carbon fiber. Carbon fiber random mats and discontinuous fiber yarns. Also preforms.	www.elgcf.com
Competitive Green Technologies	Uses natural fibers with PP and PE based polymer matrices and bioresins	Coffee beans, and some bio materials	Biocomposites like biodegradable bins, biodegradable cases, and carbon-based products.	www.competitive-greentechnologies.com
CFK Valley Stade Recycling, Germany	Pyrolysis, > 1000 t/year, launched in 2011. Presorting, crushing, and sorting of materials according to type of fiber and state of processing: Dry carbon fiber scraps, prepreg materials, end-of-life parts. Pyrolysis using thermal treatment excluding oxygen to recover pure carbon fibers completely by means of thermal oxidation of pyrolysis gases.	CFRP waste materials of different types	Milled 80–500 μm . Fiberball/pelletized/chopped 1–100 mm (e.g., for PA, PC, PP reinforced compounds). Wet laid veil 10–30 g/m ² (e.g., for surface optimization, EMI shielding). Air laid nonwovens 200–600 g/m ² (e.g., for RTM process for structural parts, SMC & BMC process). Refined custom-made fiber surface. Cutting and processing of carbon fibers into models “chopped” and “milled” accurately cut to desired fiber length.	www.carbonxt.de , http://cfk-recycling.com , https://www.cfk-recycling.de/index.php?id=57
Materials Innovation Technologies – Reengineered Carbon Fiber (MIT-RCF), South Carolina, USA	Pyrolysis, current capacity 2000 t/year recovered carbon fiber output (room for expansion)	All kinds of CFRP waste materials	Nonwoven rolled goods. Chopped fiber for compounding and long fiber-reinforced thermoplastic (LFT) applications. Preforms (3-DEP process).	http://mitrcf.com
Reprocover, Belgium	Thermoset waste ground to max. 6 mm granules. 30% glass fiber flakes mixed with 70% thermoset granules, resin added, high pressure cold molded.	Thermosets, including GRP with or without fiber-reinforcement. Also wastes from dry glass fibers.	Utility boxes, rail infrastructure products (e.g., cable tray covers), flower boxes, bins, etc.	www.reprocover.eu
Global Composites Recycling Solutions, UK	Ground GRP and glass fiber is incorporated with other materials into Ecopolycrete. This is to be sold as a mix for polymer concrete type applications that can be precast or poured in place for railway sleepers, parking stops, and other construction products. The material has a steel-like compressive strength and very high fire resistance. Went commercial in Tennessee, USA, around September 2014, and later in Northamptonshire, UK.	Cured GRP and glass fiber	Ecopolycrete	www.ecopolycrete.com
Global Fiberglass Solutions, Bothell, WA, USA	Recycling services to industries worldwide, including the wind energy, aerospace, maritime, and manufacturing sectors. Infinitely recycles with GFS process.	Industrial carbon fiber and fiberglass waste	Wind blade recycling, ecopoly pellets, fiberglass recycling	https://www.global-fiberglass.com/

Hambleside Danelaw, UK	Have developed a process for mechanically recycling GRP to retain fiber length. These fibers have been utilized to form reinforcements both as chopped fiber and in nonwoven recycled fiber mats. The fibers have been used in both thermoset and thermoplastic composites to form products for the construction industry. Experimentation has also been carried out in using the fibers with concrete and with rubber to enhance the properties of these materials.	Cured GRP	GRP products, roof lights, cladding flashings, and the Dryseal flat roofing system.	https://www.hambleside-danelaw.co.uk/
Extreme Eco ₂ Solutions, Netherlands	Have started collecting production and end-of-life waste, working with selected partners in the transport and dismantling sector. The intention is to shred the GRP and grind to powder. This would be transported to Norway for recycling, initially as an additive for polyethylene film products in a process that is under development.	Cured GRP including whole products (e.g., boats)	–	http://extreme-ecosolutions.com
Karborek RCF, Martignano, Italy	Pyrolysis process with energy recovery, to produce chopped/milled carbon fibers and carbon fiber felt. Capacity up to 1500 t/year. The plant was completed in October 2014, and production started around January 2015.	CFRP waste	Chopped carbon, milled carbon, fibers, and carbon fiber felt.	www.karborekrf.it
Carbon Fiber-recycle Industry Co Ltd, Japan	Utilizing thermal decomposition by self-combustion process (6.7 MJ/kg-CF, 13.2 MJ/kg-CF), the company expects a recycling output of 1080 t/year.	CFRP waste	Recycled carbon fiber (and at pilot scale at time of data collection for other products).	https://cfri.co.jp/en/
Carbon Conversions (formerly MIT-RCF), South Carolina, USA	Milling and flocking, thermoplastic compounding and for SMC and BMC (high strength recycled carbon fiber-requirements, prepreg, closed & open mold infusion, thermoforming, pultrusion, compression molding, thermoforming closed mold infusion)	CFRP waste	Chopped fiber, and nonwoven mat.	https://carbonconversions.com
Viridor, Oxford, UK	It separates glass, plastics, and polymers by polymer type including PET, HDPE, and PP pots, tubs, and trays	Plastics, glass, composites and other polymer wastes	EfW (energy from waste), some polymer products.	https://www.viridor.co.uk
Eco Waste Solutions, Burlington ON, Canada and Dublin, OH, USA	Uses a starved-air (pyrolytic style) process to convert the waste into a gas. Small waste generators with 100 kg to 15 t per day are best served by the EWS batch load waste system.	General wastes including composite wastes	EfW, some polymer products.	https://ecosolutions.com
Veolia, Rostock, Germany	Collection, sorting, then shredding to obtain PET flakes and washed in hot water. A mechanical and chemical recovery process transforms the flakes into a product suitable for food use. They are then purified before being packaged for shipment to bottle manufacturers. Up to 50% of recycled PET can be used to produce new bottles.	Plastic bottle wastes	PET flakes.	https://www.veolia.de
Reciclaia Composite, Madrid, Spain	Recycling company that optimizes composite waste management and minimize your carbon footprint	Carbon fiber and glass fiber wastes	Recycled fibers.	https://reciclaiacomposite.com

Abbreviations: BMC, bulk molding compound; CFRP, carbon fiber-reinforced polymer; GFRP, glass fiber-reinforced polymer; GRP, glass reinforced polymer; HDPE, high density polyethylene; LFT, long fiber thermoplastics; PET, polyethylene terephthalate; PP, polypropylene; SMC, sheet molding compound.

Note: Abramovich, H., 2017. Chapter 1 – Introduction to composite materials. In: Stability and Vibrations of Thin-Walled Composite Structures. Oxford, UK: Elsevier. pp. 3–4. doi:10.1016/B978-0-08-100410-4.00001-6.

aerospace, defense, wind energy, automotive, and sport. Specific examples of applications include aircraft wings (Wong *et al.*, 2017; Smith, 2013; Shi, 1996), wind turbine blades (WindEurope, 2017; Wong *et al.*, 2017), Tension Leg Platform tethers (Engineering and Freyssinet, 2000; Johnsrud, 1999), composite risers (Pham *et al.*, 2016; Amaechi *et al.*, 2019a,b), automotive (Akampumuza *et al.*, 2017; Vo Dong *et al.*, 2015; ELG Carbon Fibre, 2019), and tennis rackets.

According to Wise and Girard (2016), there are three main factors that influence the economy of carbon fibers. The first is the continued expansion in the market, especially in sectors such as automotive. Second is the drive towards a more cost-effective, high quality fiber that can be manufactured in large volumes. Thirdly, the availability of sustainable carbon fiber sources, including renewable precursors and routes for recycling carbon fibers from composites.

However, the challenge of recycling GRP, such as these waste trims and powdered wastes from the composites, is a stumbling block in industries where the pressure to recycle is high, as shown in Figs. 2–5. In Europe, the different processes have been tabulated to show the production volume from 2008 to 2018 by Industrievereinigung Verstärkte Kunststoffe - Federation of Reinforced Plastics (AVK) market reports, as presented in Table 4 (Witten *et al.*, 2018; Sauer *et al.*, 2017; Witten *et al.*, 2016, 2015; Witten and Jahn, 2013; Jahn *et al.*, 2012; Witten and Jahn, 2011). It shows that there is an increase that is a function of the global economy, as a decreased production was recorded in 2008–2009. Some advances in the use of biocomposites show that they can have good strength for offshore applications, as shown in Table 1.

Review on Offshore Composites

It is pertinent to discuss the applications of composites in the offshore industry in general. A suitable application for a composite riser configuration like this would be marginal fields. Smaller vessels and lighter, redeployable risers would dramatically lower the cost of small pool field development and make these smaller reserves economically feasible. Composites are currently beating digital cameras on the innovation front – around a decade from inception to the first consumer product rather than 15 years. Changing attitudes toward the technology may be a driver for this and it were not be long before riser applications, in the form

Table 3 Typical properties of mostly used reinforced continuous fibers

Material	Trade name	Density, ρ (kg/m ³)	Typical finer diameter (micro μ)	Young's modulus, E (GPa)	Tensile modulus (GPa)

discussed or otherwise, will begin cutting costs in the oil and gas industry. Composites can be classified for matrix/reinforcement and by manufacturing process, as illustrated in Figs. 6 and 7, respectively. Due to the technological developments, composites can be reused and recycled, as presented in Fig. 8. An application of the state-of-the-art on composite materials in the offshore industry, is shown in Fig. 9.

The renewable composites used in the offshore industry are mostly limited to wind turbines, and lightweight composites used in offshore structures. There are challenges with using renewable composites on ships and offshore platforms due to restrictions

with the standards. Basic structural members in most of the offshore standard recommend the use of steel members, as the main reinforcing and load-carrying member of the platform ([Tables 3](#) and [5](#)).

Historically, the Chinese were the first to create oil pipes, using bamboo trunks as conduits from local oil wells. This trend later led to development of more sustainable materials that can be used to transfer oils. Thus, steel pipes came into existence. However, with the need to lighten the weight of the structures as explorations move deeper, composite risers ([Amaechi et al., 2019a](#); [Amaechi and Ye, 2017](#); [Gillett, 2018](#)) are potentially a good option. Due to the different environmental conditions for oil explorations, such as that

may be harsh, benign, or squall, there are advances in the application of offloading systems adopted recently like Chinese lantern configurations (Amaechi *et al.*, 2019b) and lazy-S configurations (Amaechi *et al.*, 2019c) on CALM buoys. These systems have hose connections that are used to transfer oil and other fluids offshore and onshore. The materials used in the making of the offshore vessels and the submarine hoses have also composite materials in them. Airborne Oil and Gas (Jak, 2018; Smits *et al.*, 2018; Spruijt, 2018) and Magma Global (Wilkins, 2016; Hatton, 2012; Mintzas *et al.*, 2013) are currently two companies that have developed these offshore structures called composite materials.

The offshore industry has seen different technological advancements in recent years, which started when oil explorations in Texas and California increased creating more opportunities in oil, rather than gold. In the Gulf of Mexico (GoM), the Stone FPSO operates in 2926 m while the Perdido SPAR platform operates in 2450 m as they are currently the deepest offshore structures as shown in Fig. 2. However, there are still more developments on different offshore structures, as shown in Fig. 3.

Despite these applications of composites in the offshore industry, the industry has not been at the forefront in leading on the advances in composite applications. Some other industries have applied composites for decades successfully to improve performance and safety, like using composite handrails on ships. The marine industry has increased in the application of composites in hull making for ships, yachts, and leisure boats. However, the aerospace industry has notably used composites double every five years since 1987 (Murray, 2018). Composites have since been applied to the oil and gas industry (offshore and marine industries included), as they have changed the landscape of the industry. This allows reduction in airframe weights, less operating costs, and fuel savings. Composite materials are lightweight, with weight reduction ranging from 20% to 50% (Murray, 2018). The main characteristics of composites that make them more suitable in the composite industry are presented in Tables 3 and 5, for reinforced composites and biocomposites, respectively.

Dressed Landing String Joints

Landing String Solutions (LSS) LLC developed the concept of applying composites in their landing string scheme, and thus were the first in the offshore industry to use composites in buoyancy for landing strings. This concept provides the option of improving safe rig operations, optimizing critical path time and significantly decreases cost by reducing the hook load while running heavy enclosures and buoyancy casings (Murray, 2018). The challenge was to get the suitable material that will not be affected by the wellbore fluid used during drilling. It is important that all composites used in all drilling operations are very suitable for use in seawater. Secondly, drilling mud has a different mix of chemical components with their varying temperatures too.

Buoyancy Modules

Trelleborg developed some of their buoyancy modules for oil drilling and offloading operations using polymer-based composites that are syntactic buoyancy materials. The raw materials used include hollow glass microspheres powders that are talcum-looking

Fig. 6 Classification of composites by (a) matrix, and (b) reinforcement.

but of high strength glass bubble. The material is also used in aerospace applications because of its high strength characteristics. For the buoyancy modules, it is covered by a polyurethane skin to ensure that it provides high syntactic buoyancy service.

Composite Buoyancy System

Trelleborg and LSS developed the first composite buoyancy system that is deployed on a drillpipe landing string. According to *Offshore Magazine* (2015), the system is the first application of buoyancy in drilling riser. The application of buoyancy on the landing string enhances deployment of more number of casings, reduces the rig time and also reduces operational cost. The buoyancy was successfully tested in the a testing field located in the GoM, and has been proven to be successful up to an operational pressure of 41.36 MPa (6000 psi). By design, the new composite buoyancy system was designed to offset the landing string weight up to 80% but not in all cases. "In this particular application, this is not a better mousetrap. It's not a step change. This is a new trap altogether. This is an enabling technology. The composite-based system creates buoyancy once the casing/ landing string is in the riser, which reduces the hook load, decreasing the risk of the vessel exceeding its maximum hook load rating. This gives a smaller and cheaper rig the opportunity to do the job safely which means potentially eliminating liner tiebacks and running longer casing strings" (Murray, 2018).

Composite Risers

Development of composite risers have progressed greatly from the first time composite risers were installed successfully on Heidrun platform in 2002 (Salama and Mercier, 1988; Ochoa and Salama, 2005; Salama *et al.*, 2002). Recent developments on composite risers include the composite thermoplastic pipes, Magma M-pipe (Hatton, 2012; Mintzas *et al.*, 2013; Wilkins, 2016), and Airborne composite riser pipe (Steuten and Van Onna, 2016; Onna *et al.*, 2014; Van Onna and O'Brien, 2011), composite

flowline (Spruijt, 2018 and Jak *et al.*, 2018) and composite umbilicals (VisionGain, 2014; Van Onna and Lyon, 2017). Other design concepts on composite riser end-fittings (Amaechi and Ye, 2017; Amaechi *et al.*, 2019a; Hatton *et al.*, 2013) are presented in Fig. 3. The mechanical properties of composite risers can be seen in Tables 6–8.

Composite Choke and Kill Lines

Despite the various challenges, they are gain-worthy in the industry, academia, and research institutes. Developments in offshore composites kicked off trying to improve on its application in aerospace composite researches. The issue with offshore structures is the environmental loads, such as wave, excess pressure, internal pressure, manufacturing challenges, metal composite interface

end, fittings, and weight of steel. It has been found that composites can offer some advantages on it but the thickness of the wall has to be considered because it involves high pressure high temperature, and the weight of other lines like the flow lines, choke, and kill lines (Skaugset *et al.*, 2013) all contribute to the total weight of the riser joint assembly system. Thus the need to introduce lightweight materials have been found to reduce the top tension load on the riser system (Omar *et al.*, 1999; Skaugset *et al.*, 2013; Hatton, 2012).

Benefits of Composites in Offshore Industry

Composite materials give a variety of advantages that could enhance risk technology. Composites are lightweight and provide decent levels of strength. They can be easily formed into complex shapes due to their flexibility and can provide elevated levels of fatigue resistance and corrosion resistance. Maintenance needs are relatively low, and they can be installed via reel lay. Composite materials also a low axial and bending stiffness when compared to steel. However, composite materials have high material cost with limited track record offshore unlike steel, despite widespread applications in other industries. Currently, there are few codes and standards with direct applicability to composite risers.

Some of the benefits that composites may bring to the riser industry include cheaper installation costs (due to lessened weight), lower maintenance requirements in the offshore industry, lower roughness on internal bore (offering increased flow rates), and

Table 9 Benefits of composites for some offshore applications: Composite risers, composite propellers, composite choke and kill lines, and wind turbine blades

<i>Composite risers</i>	<i>Composite propellers</i>	<i>Composite choke and kill lines</i>	<i>Wind turbine blades</i>
Offer reduced weight of buoyancy and reduced size; lightweight (m-pipe is 1/10th of steel in air, and 1/5th in water); have excellent fatigue performance; reduce the variable deck load; ease of transport and deployment, like towing on site; enable drilling operations in ultradeep water and high reservoir pressures; have smooth bore for higher flow rate; reduced subsea project risk; require no upper riser assembly for deployment; have high pressure capability; offer lower life cost and lower system cost; have improved corrosion resistance	Enhance some weight saving on the ships; enhance fatigue performance of the structure; enhance the inception speeds with the use of thick flexible blades; enhance vibration-damping characteristics; enhance easier fabrication into more complex shapes; reduction of cost for fabricating the blades; reduction of the through-life maintenance costs; reduction of corrosion issues; reduction of noise signatures; reduction of electrical signatures; reduction of magnetic signatures; reduction of corrosion issues; reduction of wear on the shaft and gearbox; reduction of steel parts used in the propeller connections	Can have increased ID of choke and kill lines with same weight; extend operational envelope of an existing drilling rigs; have excellent fatigue performance; reduce the variable deckload; store more riser joints on the deck; have increased mud flow rate and better well control	Reduction of cost for fabricating the blades; reduction of the through-life maintenance costs; enhance some weight saving on the turbine; increase energy efficiency; ease installation of wind turbine; easier to form into complex shapes; low field life; less maintenance cost; resistance to corrosion; resistance to conductivity; resistance to fatigue damage; long field life; high-impact resistance; thermal stability; tolerance to damage

reduction in vessel hang-off loads (Hopkins *et al.*, 2015, 2014; Saleh, 2015). Despite these benefits, replacing steel with composite materials is unlikely to reduce the costs for existing designs. The real advantage composites offer is as an enabling technology for new concepts and operations in challenging locations and environments. Further concerns relate to damage to the sublaminar, which is hard to inspect on a manufactured pipe, and to the challenges of making up connections and end fitting design. A comprehensive review on the benefits of composites on some offshore applications is presented in Table 9.

Recycling Process of Renewable Composite Materials

There are different processes that are considered in the recycling of renewable composite materials in the composites industries that are beneficial for the offshore industry. There range from mechanical to thermal processes, as discussed in this section. Different literature present development of pyrolysis-based carbon fiber-recycling processes and these are now commercially available in several places since the launch of Milled Carbon (presently known as ELG Carbon Fiber) located in the West Midlands, UK (ELG Carbon Fibre, 2017; Job *et al.*, 2016; Job, 2013). However, the economic value of carbon fiber is about 10 times that of glass fiber. This inadvertently affects the commercialization of these recycling processes, making it quite challenging. It is noteworthy to state that although commercializing it has been a bit difficult, it has been “easier” than finding recycling routes for GRP, despite the much smaller volumes. According to AVK 2018 market report, in 2018, the carbon fiber-reinforced polymers (CRP) were estimated at 128,000 tonnes while the total European GRP market had an estimated total of 1.141 million tonnes with predicted growth rate of 2.1 % (Witten *et al.*, 2018). This was higher than that of the AVK 2012 market report, which presented 76,000 t of CRP compared to about 1 million tonnes GRP parts produced in Europe in 2012 (LinseT, 2013; Job, 2013; Sauer *et al.*, 2017).

The recycling process supported by European Composites Industry Association (EuCIA), and available in Germany, involves the addition of GRP waste to cement kilns. This gains value from all parts of the composite and is commercially active in Germany through the route known as Compocycle, operated by Zajons and feeding Holcim’s cement kilns. However there is still a significant gate fee for the process. In Germany regulations leave no option to landfill so the volumes of GRP waste are sufficient to justify such a process. Composite manufacturers such as Fiberline in Denmark have supported that process, being close enough to take advantage of it. But this route reduces the value of the material to that of calcium carbonate and at present is not economic compared with landfill where landfill is an option.

There are several processes that are either commercially exploited or under development whereby discontinuous fibers are converted into intermediate products. Several companies produce nonwovens using short carbon fibers. In many cases these are still virgin fibers and come from offcuts, weaving selvedge, etc. The nonwoven textiles can be made by the air laying, carding, or wet-laid processes. The other approach being employed is to chop the fibers to a fairly short length (a few millimeters) and then mix these with either a thermosetting resin to make a sheet or bulk molding compound or with a thermoplastic melt to produce a compound for injection molding. Care has to be taken during mixing to avoid fiber breakage. Recovery of the fibers from parts already impregnated with resin is more complex, but can be done by pyrolysis or solvolysis. The advantage of these recycling solutions is that it will lower the cost of carbon fiber (Holmes, 2017; Boucherat, 2016). According to an ELG Carbon Fiber report, 30% of the carbon fiber manufactured worldwide each year becomes waste, which is equal to about 18,000 tonnes per year. The carbon fiber industry has moved away from being a niche industry only producing 100 tonnes per year; as such the issue of waste needs to be tackled.

Recycling, which is a means of returning the material back to the composite market, will create the possibility for stability, longevity, and extra source of supply to the industry.

Mechanical Recycling Process

The composite waste is first sorted then it is milled or ground using a hammer mill or related tools to obtain the required sizes. Researches on mechanical recycling show that energy is used in this process (Howarth *et al.*, 2014). The reduction of sizes is used to convert the grades of the wastes into different fractions and then it is sieved into powders. Different fractions of the fillers and ground resins as well as other fibers of varying lengths are all embedded into the resin. Also contained in the recyclates are flakes of the materials, which are seen in SMC, BMC as seen in GRP composite wastes. One drawback here is that this method has very limited applications on CFRP composites. The ground composite materials are used for either fillers or as reinforcements. The fillers are not considered to be commercially profitable because of the low cost of the virgin fillers, for instance, silica and calcium carbonate. These fillers, which are the recovered powders from the mechanical process after sorting, can be incorporated into new materials. However, it must not be more than 10% in weight due to the breaking down of the molecules as a result of deterioration of the mechanical properties as well as more problems associated with processing higher filler contents due to higher viscosity of the compound. To this end, they have been applied as alternative energy sources due to the high organic compositions of the resins used. Fig. 14 shows the steps carried out during mechanical recycling.

Recycling of GRP by mechanical grinding has been ongoing for some decades. As far back as in the 1970s, the late Wolfgang Unger was developing his proprietary Seawolf technology in Florida in the United States, to grind fiberglass scrap and use it for replacing rotten boat transoms or incorporate it using spray-up equipment for making bathtubs and other products (LinseT, 2013). Unger's company is now called Eco-Wolf (Unger, 2011) managed by his daughter Sabine Corinna Unger. Eco-Wolf in 2011 partnered with Global Fiberglass Solutions, which is seeking to build and manage facilities to collect and recycle fiberglass across the United States, having developed applications such as railroad ties (railway sleepers), just like Reprocover and 3B fibers did.

Another commercial outfit was ERCOM Composite Recycling GmbH established in Germany in 1990 to recycle automotive production and postuse waste by shredding and grinding graded parts into powder, to be used in new sheet molding compound (SMC) in proportions up to 20% (Marsh, 2001). ERCOM terminated in 2004. This approach of grinding GRP to fine powder for use as filler is well established in several industries, but as with the cement kiln route, it reduces the value of the material to that of calcium carbonate, which can be purchased at very low cost (around £200/t). In addition, it requires a significant amount of energy input to grind the material finely. Thus apart from some in-house recycling (see below), attempts to commercialize this as a recycling route have failed.

Thermal Recycling Process by Pyrolysis

Pyrolysis, according to Sponberg (1999), is the process of chemically decomposing or transforming a material into one or more recoverable substances by heating it to very high temperatures in an oxygen-depleted environment. This process differs from incineration, which is carried out in an open atmosphere. Pyrolysis is a thermal process that is carried out at a temperature range of 450–600°C, subject to the environmental conditions and the resin used. In other words, pyrolysis is the decomposition of the resin using heat. This can be achieved by applying a batch process with the use of an inert atmosphere or vacuum. This decomposes the resin to a mixture of chemicals, which tend to volatilize from the resin and then condense in the outlet as pyrolysis oil, which can be burnt as a fuel or distilled to recover chemicals. Although, the process also generates a char which is a hard glassy (noncrystalline) carbon and this can be well adhered to the fibers and bond fibers together. The higher temperatures are used for the epoxies and thermoplastics of high performance like PEEK composites, while the lower temperatures are used for the polyester resins. Thermal degradation of the resin matrix produces oil, gases and solid products made up of fibers, char and possibly fillers. To reduce the amount of char produced, it is oxidized using small quantity of oxygen. Char can only be removed here by oxidation. With this method, the recovery of fibers, fillers as inserts are possible (Job *et al.*, 2016; Castro *et al.*, 2013; Thakur *et al.*, 2007). The breakdown of the resin into molecules of low-weight, lower-weight, and much lower-weight produces the gases and oil fraction, which can be recovered chemically into other chemicals, and sometimes burnt to generate energy such as EfW energy recovery processes. Pyrolysis has been successfully applied on plastic wastes as well as composite wastes (Sekula and Leszczynski, 2009; Kennerley *et al.*, 1995) as well as in the offshore industry (Demirbas and Taylan, 2015).

As stated earlier, the product from pyrolysis depends on the conditions, and thus affects the resulting mechanical properties of the fibers. For glass fibers, the tensile strength can be varied between 52% and 64% while the tensile strength of carbon fibers can be varied between 4% and 85%. This shows the influence of temperature on the resulting fiber properties. A pyrolysis temperature of 450°C is usually the lower limit while the temperature range between 500°C and 550°C appears to be the upper limit of the thermal process of pyrolysis. As this temperature range, an acceptable fiber strength that is typically viable commercially for carbon fiber is achieved.

Any thermal or chemical process strips the sizing off the fibers. In the case of glass fiber, this results in dramatic loss of strength and handling/processability. Thus, thermal and chemical treatments are not suitable for GRP unless the fibers are posttreated. A

Table 10 Comparisons between different recycling technologies

<i>Recycling technologies</i>	<i>Strengths</i>	<i>Weaknesses</i>	<i>Points of attention</i>
Mechanical recycling	Efficient waste management process (high throughput rates)	High decrease of (mechanical) properties Material undergoes downcycling Recyclate with a high content of other material (including polymers, contaminants, paint, coatings) Small, unstructured, coarse, and nonconsistent fibers High operational costs and capital investment (running costs, installations) Has up to 40% material waste	It requires full use of PPEs. Fine dust released into the surrounding atmosphere. Potential of fibers to stick into human skin or mucous membranes causing irritation.
Pyrolysis	Pyrolysis gas and oil can be used as energy source making it a self-sustained process Wax recyclate can be used as fuel or intermediate for chemicals production Easily scaled-up to multitonne capacity Microwave pyrolysis involves heating the material at its core with microwave radiation It creates room for easier control of the heating process leading to decreased induced damage to the fiber material	Fiber product may retain oxidation residue or char Sizing degradation of glass fibers leads to changes in the composition (chemical structure)	Potential combustible gases leakage from waste treatment chambers
Cement kiln (coprocessing)	Highly efficient and fast process: Residence time of 4–5 s in cement kilns Large quantities can be processed Up to 75% substitution of cement raw materials which significantly reduces CO ₂ that is emitted by the cement industry No ash left over, minerals are trapped in the matrix of the clinker	Complete loss of material characteristics (fiber form) High processing temperatures	Emissions from pollutants and particulate matter
Solvolytic	Recovery of clean fibers in their full length Recovery of resin (like polymers or oligomers) that can be reused	Insufficient efficiency (throughput) of the technology High energy consumption due to the high-temperature and high-pressure Use of large amounts of solvents	Gas emissions (depending on catalysts potentially toxic, e.g., from alkali catalysts) Human health impact and ecotoxicity High water consumption (although reuse options could be explored)
High voltage pulse fragmentation	Able to treat industrial quantities, which produces sufficient scalability of the process to treat larger capacities Low investments required to reach the next level	Only laboratory- and pilot-scale machines are available Heavily decreased modulus of glass fibers	Working near high voltage
Gasification (fluidized bed)	Highly flexible (in terms of different process capabilities) and simple process High efficiency of heat transfer	Low fiber qualities for glass fibers (significantly reduced fiber tensile strength) Will only be economically viable if it reaches capacities of more than 10,000 t per year (Yang <i>et al.</i>) Defluidization is problematic: Fluidized bed can locally collapse	Emissions (e.g., CO ₂) related to the process Quite stable and efficient performance in case of reactor operability and safety concerns

Abbreviations: CO₂, carbon dioxide; PPE, personal protective equipment.

Fig. 11 Image of space rocket module in NASA facility, USA.

posttreatment to recover glass fiber properties after thermal treatment has been proposed in literature (Thomason *et al.*, 2016; Bashir *et al.*, 2017; Tajeddin, 2017) as well as other methods to recover the strength of the glass fibers. According to Job *et al.* (2016), an increase in the scale upwards to produce glass fibers that can compete with virgin glass fibers would require the substantial application for chopped glass fibers, for instance, automotive thermoplastic composites. However, it is difficult to achieve this without economic loss, because glass fiber has comparatively low value. There are three novel methods in pyrolysis, namely continuous pyrolysis, chain conveyor pyrolysis, and fluidized bed pyrolysis.

Continuous Pyrolysis

To achieve the continuous pyrolysis, the process has to have steady supply of high temperature. Carbon fibers are comparatively oxidation-resistant up to about 500°C, thus it is possible to burn off the resin and with careful control of the conditions inside the furnace still avoid a significant loss in strength. This is the method employed at ELG carbon fibre company (ECF) in a patented furnace process called continuous pyrolysis. Combustion of the resin depletes the oxygen levels in the furnace so the oxidation of

the fiber is minimized. The presence of oxygen minimizes char formation because entropy considerations do not favor char formation over combustion and any char that is formed oxidizes faster than the fibers. Regardless of how the fibers are won from the waste, they are liberated as discontinuous, poorly aligned fibers. Subsequent processing is necessary to take this low bulk density material to convert it to products that the industry wants to buy (Harris, 2017; SNW, 2019).

Thermal Recycling Process by Solvolysis

Solvolysis has also been applied to recycle composites and plastic polymers as a chemical process (Prinçaud *et al.*, 2014; Oliveux *et al.*, 2017; Yang *et al.*, 2014). In solvolysis the resin matrix is decomposed or dissolved by a solvent. As composite resins are generally engineered to be durable in typical service conditions, they tend to have excellent resistance to chemicals. Dissolving the resin therefore requires aggressive chemicals and/or elevated temperatures and pressures. For example, it is known that carbon

fibers can be liberated from an epoxy laminate by boiling it in concentrated nitric acid for several hours (ISO 14127). It has also been proven that a supercritical acetone/water mix (320°C, 170 bar) also dissolves the resin. Neither method has been scaled up to tonnage quantities and there are still significant challenges to be addressed before this technology becomes commercially viable.

Thermal Recycling Process using Cement Kiln

The application of cement kiln in recycling glass fiber composites is one of the recommendations of EuCIA (2011). According to the European Composites Industry Association (EuCIA), GRP is “recyclable and compliant with EU legislation.” The process of incineration of the GRP wastes is impractical because relatively 50%–70% of the GRP material is composed of minerals and ends up as ash, which ends up in landfills. To coprocess these using the cement kilns, the sizes of the GRP composite parts are reduced and then mixed together with other composite wastes to introduce into the cement kilns. Typical GRP composite is made up of E-glass, which is mostly aluminoborosilicate, organic resin, and some calcium carbonate filler. Once the mix is sent into the cement kiln, the organic resin burns providing energy (about 12 MJ/kg of waste) while the mineral constituents provide feedstock used as the cement clinker (LinseT, 2013; Job, 2013). Usually, the clinker is ground to form cement paste or powdered cement, and the calcium carbonate calcines (which releases

Fig. 16 Summary of renewable materials vs. oil production indicating stages of energy input. Reproduced from Eichhorn, S.J., Gandini, A., 2010. Materials from renewable resources. *MRS Bulletin*, 35(3), 187–193.

carbon dioxide) to calcium oxide, which is the primary component of Portland cement. Alumina and silica also have cementitious properties in an alkaline environment and are typically present in Portland cement at about 25%, and in much higher proportions in cement alternatives from fly ash and slag. Boron, which is found in most E-glass, can cause a reduction in early strength during the setting of cement, but as long as proportions are kept low it is not considered a problem (Pickering, 1993, 2006).

Comparisons Between the Recycling Options

Considering the different recycling options discussed, we can use a diagram to compare the different recycling options, as presented in Fig. 15 and Table 10. Different researches have been reviewed to attain the results on the comparisons between the recycling options. Details can be found in literature (Liu *et al.*, 2017; Pickering, 2006; Oliveux *et al.*, 2015) (Tables 7, 8 and 10).

Case Study of Energy for Waste

Waste minimization, reuse, and recycling are essential to achieve more sustainable waste management. There are, however, technical and commercial reasons why all waste cannot be recycled. There will always be some residual waste. It is important that local authorities and businesses have a way to manage residual waste and recover maximum value. There is a view that EfW is competing with recycling. Experience across Europe shows that best practice can involve high levels of recycling combined with EfW for the remaining waste that cannot be reused or recycled. Switzerland, the Netherlands, Sweden, and Denmark, for example, all have high levels of EfW as an integral part of their waste management strategies. These countries also have high waste recycling rates. Fig. 10 is an application of offshore wind turbine which can be used in the description of the EfW process (Eichhorn and Gandini, 2010) (Figs. 11 and 12).

Case Study of Building Recycled Boats

One of the earliest reports made of building recycled boats was first noted in Sweden (Sponberg, 1999). According to the author, Ryds Battindustri AB, the Swedish largest boatbuilder as of 1999, was producing about 3600 small powerboats yearly in 36 models ranging in size from 3.3 m (11 in.) to 5.95 m (20 in.) using a lot of fiberglass composites. Ryds partnered with the Swedish Institute of Composites to develop on manufacturing boats using closed loop recycled scrap, which accounted for about 10% of its layup production. The result was a 4.75 m (15.5 in.) concept boat, containing about

Fig. 17 Mechanical recycling of wind turbine blades after demolition, in pretreatment stage. Courtesy: Source: Estevez, D.G., 2019. Demonstration of wind turbine rotor blade recycling into the coal clough windfarm decommissioning opportunity. 20% recycled fiberglass by weight. The original single-skin laminates of sprayed-polyester fiberglass in the hull and deck were cut back by 50% and replaced with a sprayable polyester mixture containing 33%–40% ground scrap. Scrap mixture was used to replace the core materials, such as Coremat, plywood, and Divinycell. The boat's laminates had equal or better strength in all respects and, where the recycled compound replaced plywood, screw-holding power improved significantly. Other applications of composites can be seen on offshore ind turbines, NASA's space craft modules, offshore composite risers and leisure boats (Figs. 10–13).

The equipment for processing the scrap mix includes a grinder, a high/low shear mixer, and eight specially designed spray equipment (see photos above), all developed by and licensed from Seawolf Industries, which is owned by Wolfgang Unger. The grinder can quickly grind scrap to predetermined fiber lengths and keep fibers intact, which is important to the strength of boat laminates. In addition, compound additives developed by Seawolf resolved problems of premature catalyzation, viscosity, and fibers settling to the bottom of the mix. Seawolf now sells its machinery to any fiberglass manufacturer who wants to start recycling. Ryds anticipated its concept boat would go into production at about 50 boats per year. Unfortunately, recycled production boats did not go on as they planned at that time (Sponberg, 1999). Over time, other boat makers started to try fiberglass recycling.

Offshore Wind Turbine Blade Recycling

The recycling of wind turbine blades involves the integration of innovative remanufacturing technologies addressed to develop profitable reuse options for mechanically or thermally recycled EoL GFRP and CFRP composites. Different steps are involved in mechanical recycling process of composites, as illustrated in Figs. 14 and 15. Each process has its limitation and process capacity, as presented in Tables 1 and 10, depending on the source of raw materials and the recycling company's capacity.

Challenges of Recycling Renewable Composites

The renewable composites used in the offshore industry are not limited to lightweight composite pipes and offshore wind turbine blades, as illustrated in Figs. 13 and 15, respectively. Despite the application, there are challenges that are faced in composite applications in the offshore industry. According to ECF, the main challenges in recycling carbon fiber composites have included dealing with the complex nature of the waste streams. Even relatively clean waste streams from composites manufacturing still contain resins of varying chemical composition and unwanted materials such as paper or plastic backing films, and the recycling process has had to be optimized to ensure the complete removal of these unwanted materials without damaging the fibers. The second challenge is classification of the fibers. The composites industry has grown up with a wide variety of carbon fiber grades available from different manufacturers. Although the recycling process has only a small effect on the properties of the fiber, it is not desirable to retain the original fiber designation after fiber recovery. ECF has addressed this by introducing a generic classification system based on the Young's modulus and tensile strength range of the recovered fibers. Wind turbine blade recycling and reuse is a current practice in the industry. In addition, other natural renewable materials can also be sourced and recycled such as basalt and flax. An example is presented in Fig. 16, depicting the stages of energy input and recycling from agro industry and the oil

Fig. 23 The result from recycling a wind blade made of glass fiber. *Courtesy: Reciclaia.*

and gas industry. More wind turbine wastes generated are also disposed to recycling plant, as shown in [Figs. 17–23](#). According to [Liu and Barlow \(2017\)](#) the expected blade material usage in the future will continue to increase, as shown in [Fig. 24](#).

Qualification

First is the issue of qualification of the offshore composite structures ([Skaugset et al., 2013](#); [Wilkins, 2016](#); [Johnson et al., 1998](#)). Based on the qualification process that is applied in the development of composite structures and the failure mechanism that can occur after testing, these may be as a result of the design load not in line with predictions, failure predictions as a result of coupon strength, the type of loading (collapse, burst, bending, or long term loading). This can also be seen in the cycles depicted in mechanical recycling of composites by [Estevez \(2019\)](#) and [Garcia and Arcarazo \(2019\)](#), as depicted in [Figs. 18–21](#). An example of the product of recycling wind turbine blades is presented in [Fig. 23](#). Other applications of recycled composites is on the railway track as shown in [Fig. 25](#). With the increase in the researches on recycled composites, more qualification is expected on application of recycled composites on ship decks and cars, as presented in [Figs. 26 and 27](#).

Standardization

Another issue is standardization; however, newer standards are under development ([Van Onna and Lyon, 2017](#); [Gibson et al., 2002](#); [Echtermeyer and Steuten, 2013](#)). In boats, FRP composites have been in use about 70 years as boat making materials. Thus, most boats and motorsports are made from composites and even half of the structural airframes of modern aircrafts, like the Boeing 787 Dreamliner and the Airbus A380. They have also been used in the automobile industry as seen in [Table 2](#). FRP bridges also have been in existence for over a decade. Composites have been an enabling technology in the offshore industry, as seen in wind turbines blades and oil wells with deeper risers. However, while the standards allow

Fig. 24 Predicted blade waste in Europe until 2050. Reproduced from Liu, P., Barlow, C.Y., 2017. Wind turbine blade waste in 2050. *Waste Management* 62, 229–240. doi:10.1016/j.wasman.2017.02.007.

small boats, leisure boats, and work boats to be built using composites, the IMO and SOLAS regulations restrict the use of composites and greatly prohibits the structural use of composites due to reasons like combustibility (Job, 2015, 2014). Currently, some recycled wind turbine blades are used in making pedestrian bridges, to show that they are structural of high strength, although the service life is not high.

Conclusion

Carbon fibers and glass fibers are high performance materials widely used in many fields thanks to their specific properties. As a result, research and development in this field is very active and one major driver is cost reduction. However both FRP and GRP do not have equal amount of usage as renewable offshore composites. This study has looked at major offshore applications of renewable composites in the industry, and a brief history of their usage and recycling technologies. Some comparative studies were

also presented on the technologies and their options for a circular economy. For easier reference, this study also present some current commercial recycling facilities as well as some composite facilities, but not a fully comprehensive list due to the scope of the work.

Acknowledgment

The authors gratefully acknowledge the funding support of Lancaster University Engineering Department, Lancaster, UK, and Niger Delta Development Commission (NDDC), Nigeria. The research reported in this paper is part of the Project 51879143 supported by the National Natural Science Foundation of China (NSFC). The financial support is highly appreciated. We also acknowledge all the support from Dr. Marco Longana from Bristol Composites Institute for some reference materials and Peggy Malnati for the original images of automotives reproduced in Fig. 27 with help with obtaining the permission from SPE Automotive Division, Ford Motor Co. and Hyundai Motor Group, General Motors Co. We also thank all those who granted us permission to use their images in this project and also appreciate all who worked on the market reports on composites which were used in this study. Lastly, the authors acknowledge Stephen Hatton of Magma Global and Martin Van Onna of Airborne Oil & Gas for technical supports on composite risers.

Introduction

Nowadays logistics is a core area for companies which is concerned with transporting products between parties. However, the problem of this sector is that its scale may lead to delays and defaults in the delivery of goods as well as other issues. In addition, large distributors need a large volume of workers to meet all the demands of stores. All this may contribute to big delays in order processing and increases the possibility of losing orders (Li, 2016). In an attempt to solve this problem, companies have automated all their processes, contributing to a significant increase in the number of businesses and distributors in the logistics sector. However, an increase in the amount of digitized data and the expansion of Internet companies means that the risk of attacks on their databases is also greater. Hackers may intend to modify, steal or delete data (Chamoso, 2017; Lima, 2015).

We suggest an alternative way of solving this problem. In our case study (i.e., Garbage Utilities), we are going to consider a hybrid scenario (Li, 2014a,b). Firstly, we provide security to the data of the companies involved in the garbage logistics sector with the inclusion of blockchain. Secondly, MAS will be used for the organization's problem (Li, 2014a,b, pp. 1–8). It has been proven that MAS (MAS) provide efficient solutions to a huge variety of problems (Wooldridge, 1995). These include, but are not limited to, the use of agents for image classification (Coria, 2014), decentralized network control (Najafi, 2018), real-time problems (Carrascosa, 2008) and Internet of Things applications (Gazafroudi, 2017).

In this paper we propose a new hybrid model that uses blockchain, smart contract and a MAS to protect the data of the garbage utilities sector (Tapia, 2013) and improve logistic activities (i.e., our model allows to remove intermediaries and speed up logistics activities). In addition, multi-agents are capable of coordinating all the logistic services (i.e., our model improves organization, security and distribution times). This model is designed to improve the efficiency of the garbage utilities sector. For this purpose, data is protected and smart contracts are used to remove intermediaries (Costa, 2011) (Rodríguez, 2010). On the other hand, the MAS validates all transactions and the miners' system is responsible for creating the blockchain with the transactions made by the agent system through smart contracts (Dhuric, 2017). Although there is a lot of discussion on the use of blockchain in logistical services, there have not been any systems that would implement and evaluate it. Our approach is a functional prototype which has been evaluated empirically. Furthermore, it has been proven that it resists third-party attacks, in the case study context, more efficient than a traditional logistic model. In the methodology section, the model is proposed and in the discussion section, its advantages and disadvantages are evaluated in line with the conventional logistic model. The main contribution of this paper can be summarized as follows:

- A novel system of smart contracts to optimize the operations of the garbage logistics sector.
- A new MAS to coordinate the tasks that monitor and control the garbage logistics sector.
- A hybrid system that integrates the contributions described above to optimize the efficiency of the garbage logistics sector.

The rest of the paper is organized as follows. Section "Introduction" provides the introduction to the topic. Section "Related Work" have all the related works to this paper. The proposed system is show in Section "Proposed System". Section "Simulation Results" present the main results of our model and Section "Conclusion" show the conclusions of our findings.

Related Work

A blockchain is a distributed data structure that is replicated and shared among the members of a network (Bremer, 2017). It was introduced with Bitcoin (Nakamoto, 2008) to solve the double-spending problem. As a result of how the nodes in Bitcoin (the so-called miners) mutually validate the agreed transactions, Bitcoin blockchain establishes the owners and states what they own. A blockchain is built using cryptography. Each block is identified by its own cryptographic hash and each block refers to the hash of the previous block. This establishes a link between the blocks, forming a blockchain (Antonopoulos, 2014; Cardoso, 2017). For this reason, users can interact with a blockchain by using a pair of public and private keys. Miners in a blockchain need to agree on the transactions and the order in which they have occurred. Otherwise the individual copies of this blockchain can diverge producing a fork; miners then have a different view of how the transactions have occurred, and it will not be possible to keep a single blockchain until the fork is not solved (Santos, 2016).

To achieve this a distributed consensus mechanism is required in every blockchain network (Casado-Vara, 2018a,c,d). Blockchain's way to solve the fork problem is that each blockchain node can link next block. Just a correct random number with SHA-256 has to be found (Casado-Vara, 2018c,d), so you have number of zeros that the blockchain expects. Any node that can solve this puzzle has generated the so-called proof-of-work (pow) and gets to shape the chain's next block. Since a one-way

cryptographic hash function is involved, any other node can easily verify that the given answer satisfies the requirement. Notice that a fork may still occur in the network, when two competing nodes mine blocks almost simultaneously. Such forks are usually resolved automatically by the next block (Marín, 2015; Becerra-Bonache, 2014).

With the implementation of blockchain, smart contracts are included to make transactions between different users faster and more effective (Casado-Vara, 2018b). Nick Szabo introduced this concept in 1994 and defined a smart contract as “a computerized transaction protocol that executes the terms of a contract” (Szabo, 1994). Szabo suggested that the clauses of contracts could be transferred to code, thus reducing the need for intermediaries in transactions between parties. In the blockchain context a smart contract is a script that is stored on a blockchain (Szabo, 1997). Smart contracts have a unique address in a blockchain (i. e., they are in a block with a hash that identifies it). We can trigger a smart contract in a transaction by indicating the address on the blockchain. It is executed independently and automatically in a prescribed manner on every node in the network, according to the data contained in the triggered transaction.

A MAS is a computerized system composed of multiple intelligent agents that interact with each other. MAS are used to solve complex problems with very good results. MAS are used in a wide range of applications. Gazafroudi (2017) presents a MAS for the intelligent use of electricity in a Smart home and thus, an increase in its energy efficiency. Another problem that MAS have solved effectively is the monitoring of sound in a variety of situations. The application of a MAS to logistics is not a new problem, in Li (2018) a MAS is proposed to provide a solution to the logistical problem. In addition, another successful application of MAS is the problem of distributed computing (Banerjee, 2017). Therefore, some of the proposals that we find in the literature combine the advantages of blockchain and MAS. From a range of systems that integrate blockchain and MAS the work of Aitzhan (2018) is worthy of mention. The frame of JADE has been chosen for the development of the MAS for this project. This framework Java provides mechanisms to incorporate agents who manage safety aspects in order to measure in order that the quiet information is really the one that is transmitted and analyzes (González-Briones, 2018a,b). The architecture has been developed for the incorporation of multiple heterogeneous sensors, so that the functionality could grow in the future for the incorporation of new services (González-Briones, 2018a,b). The system is designed specifically to analyze the behavior of the user, the information of the sensors, the information of third parties and the capture of decisions.

This work proposes to use both technologies to increase security and privacy in decentralized energy networks. In Yuan (2016) authors propose a model that employs agents and blockchain for a ride-sharing system. In addition, there are other applications of blockchain and MAS. In Daza (2017) the authors propose an innovative blockchain model for IoT. However, after looking at the state of the art, we believe that the current blockchain and MAS models have some shortcomings. We propose a new model that leverages smart contracts and MAS, it is aimed at increasing efficiency in the logistics system management. This paper describes a case study which verified the proposed model, it focused specifically on logistics transport in the pharmaceutical sector.

Proposed System

This section presents the model that has been designed to optimize garbage collection with blockchain technology.

Business Model

This paper presents a new model which consists of the following elements: a blockchain in which all transactions are stored. Smart contracts that manage transactions between the different parties in the garbage utilities sector. And a that MAS coordinates all these operations. In this section we describe the how our model works. The members of each logistic operation have smart devices which monitor the status of each one. The case study was conducted in the garbage management sector, Fig. 1 shows process members. One of the parties involved in garbage logistics is the production of garbage. People buy all kinds of things and use them. In this way they produce a lot of garbage in their homes or workplaces. This garbage is placed in bins and in some cases in recycle bins to recycle the garbage. On the other hand, the waste management companies are responsible for the maintenance of the waste bins and the collection of the waste.

Once the garbage is collected, the garbage management company processes it by recycling what it can and storing or destroying the rest. In order to optimize this process, we have developed a smart contracts system based on blockchain. Performance of this platform is as follows: (1) Recycling bin. The waste that is produced is deposited in the recycling bin. When these bins are full the weight sensors detect it and the smart contract recycling bin creates a contract with the waste management utility to empty it. In this way, the recycling bin is intelligent and can be self-managed. One of the main advantages of this system managed by smart contracts is that the recycling bin will only be emptied when are needed. (2) Waste management utility. The waste management company has to collect the garbage from the recycling bin when the smart contract recycling bin runs because it has detected that it is full. Once the garbage has been collected, the smart contract waste management utility runs so that the waste management utility takes it to the recycling plant. In this way, the garbage stores are never filled and do not produce collapses in the storage and recycling of the garbage. (3) Recycling station. This is where the waste that can be recycled is recycled. At this stage of the logistic process the smart contract validates the amount of material that is introduced into the recycling plant. In the same way, the smart contract counts the amount of material that has been recycled. Therefore, the result of this smart contract will be the amount of waste that has been recycled and the amount of waste that has to be stored or destroyed.

Fig. 1 Graph based on smart contract for garbage management utilities.

Fig. 2 Multi-agent architecture. The logistic control agents are shown in green while coordinator agent is shown in blue.

Multi-Agent Model

A MAS coordinates the whole process (see Fig. 2). The architecture of the MAS is built in JADE and consists of the following layers:

- (1) Recycling bin layer. In this layer are the recycling bin. In each of them there is a BISITE PCB v.2 with a built-in weight sensor shown in Fig. 3. Thus, when the sensor detects that the recycling bin has a pre-set weight, the smart contract runs and puts that bin in a priority queue for the garbage collection trucks to include it in their path. Therefore, these agents coordinate the task of incorporating the bin into a priority list so that the bin is emptied.
- (2) Recycling Layer. In this layer the agents that coordinate it have the task of monitoring the entrance of garbage, and the exit of recycled and non-recycled garbage. That is to say, they are creating an inventory of the garbage processed to be stored and of the recycled garbage.
- (3) Waste management utility Agents. The agents of this layer coordinate that the trucks collect the garbage containers in an effective way. To do this, they create a graph with the streets and the position of the full bin, and execute an optimal route algorithm for the trucks ~cite{goldberg2005computing}.
- (4) Workflow Management layer. In this layer the agents have the task of coordinating all the other agents so that they work correctly and the smart contracts are executed when necessary.

Hardware

In this manuscript we will proceed to show the most relevant features of the BISITE PCB v.2 development board for implementation in order to cite the features in order to analyze the feasibility of its use in the case study of waste management

Fig. 3 Simulation of vehicles through a path to find full bins.

within an intelligent city. Some of the most relevant features are the sensors and electronic components included in the board, it integrates accelerometer, temperature controller, energy consumption sensor, positioning data through GPS, Galileo, GLONASS and BeiDou and also an ATSHA204A encryption chip with SHA-256 technology. The LoRaWAN network based on LoRa modulation is used as communication mode, due to its high noise tolerance and indoor penetration if necessary. The board has certain expansion ports to add sensors and/or actuators to extend the functionality of the device. These ports are specifically designed for various sensors in our case we will use the I2C input as a plug/&play. In the case study is used as load sensor Load Sensor Sparkfun also called extensometer that can measure up to 500 kg. This second version of the device has been developed with a view to reducing its size so that it can be used in a wide range of applications as an IoT device for the collection of safe data. Between the observable differences, besides the specialization of the sensors in the developed field, there is the addition of an advanced system of load management with network monitoring and the addition of an energy source such as a battery or solar.

Simulation Results

For the simulation of the model we are designing, a model of a smart city with several streets and buildings has been used. The vehicles are simulated with autonomous programmable robots that are connected with a MAS that coordinates the movements coded with JADE. In **Fig. 3** we can find several captures made on the tests that have been made in the simulations. In them the development plate presented in **Fig. 3(C)** and **(D)** (the black box) send the simulated signals to the MORE that the containers are full. In this way, the MAS creates a graph with the streets of the smart city and the bin, executes the algorithm for the calculation of the optimal routes and proceeds to their collection.

To take it to the recycling plant and garbage storage. In this way, we have seen that the routes are optimized, because instead of making a route throughout the city collecting the bin are full or not, you only go through the bin that are full. Therefore, the efficiency of garbage collection is improved. In addition, it calculates the optimal route through the city to collect only the containers that are full, therefore, also optimizes the route. That is to say, it supposes a quite remarkable improvement in the method that there is at the moment to collect the garbage in the city of Salamanca in Spain.

Conclusion

This paper presents a new Smart contract approach to improving logistics garbage services. The novelty of this paper lies in a blockchain to store all transaction information in the logistical process of the proposed case study. In addition, the multi-agent system uses smart contracts to manage the entire logistics process more efficiently, this is because smart contracts remove intermediaries. Our model can be used to improve any logistics system. The case study conducted in this proposal focuses on the garbage sector. Our model has improved security and efficiency as it is automated by the agent system. By incorporating blockchain we provide the logistics system with solid security features. Shipments can be tracked, origin and destinations authenticated, and proof of all transactions can be stored. Future lines of research include improving the multi-agent system by introducing new agents for the monitoring of procedures. In addition, our model could be enhanced by integrating a case-based reasoning system (CBR).

Introduction

Global statistics on waste tires reveal that, about 1 billion waste tires are generated every year in different parts of the world. Most of those waste tires are either burnt to produce energy or landfilled. Thermal recycling, however, is harmful to the environment because it releases more CO₂ compared to the other efforts of recycling, such as material recycling and cascaded recycling (Hazarika *et al.*, 2018). In order to encourage the recycling of waste tires that minimizes the CO₂ release, utilization of such industrial by-product in cascaded form (returning on different product) is gaining attention in recent years. It is, therefore, necessary to shift the share of recycling from thermal to cascaded recycling. When recycled in cascaded form they can be called tire derived geo-materials (TDGM). TDGM (Fig. 1) are not only low cost and low carbon (LC²) materials, but they also possess many advantageous properties such as vibration and sound absorption, good permeability, high durability and good thermal conductivity. In addition, these materials are non-dilatant in nature unlike other granular geomaterials (Hazarika, 2013). Owing to these characteristics, they can replace other conventional materials (such as gravel), in applications such as drainage, leachate, reinforcement, and so on.

For the past one decade, research related to the utilization of tires in construction projects has been gaining momentum. Due to their advantageous physical and mechanical characteristics, TDGM either in the form of shreds, chips or crumbs have been used as fill material for embankments (Humphrey, 2008), as fill material behind retaining walls and abutments (Garcia *et al.*, 2012; Hartman *et al.*, 2013), as base isolation for buildings (Tsang, 2008), and as liquefaction prevention material (Yasuhara *et al.*, 2010). The environmental aspects of such materials were thoroughly reviewed by Edil (2008).

The Japanese research covers a wide range of waste tire utilization. Few examples of those include: use of whole tires or in conjunction with other granular materials (Fukutake and Horiuchi, 2006) or use of tire chips and tire shreds (Hazarika *et al.*, 2012b; Karmokar *et al.*, 2006) and tire chips as lining in tunnel construction (Kim and Konagai, 2001). Also, tire chips mixed with cement-treated clay was used as a sealing material at a waste disposal sites in Tokyo bay (Mitarai *et al.*, 2006). Use of tire chips as a material to prevent liquefaction in soil also was experimented by Yasuhara *et al.* (2010) and Uchimura *et al.* (2008).

On the other hand, in recent years, the world has seen large scale earthquake induced hazards or climate change related hazards. Especially, in Japan, such natural hazards are too frequent in recent years. Also, in most of the developing countries, where the infrastructure development is still in infancy, adequate and cost-effective disaster mitigation efforts are urgently needed. The key issues in most of the developing countries are the balance between the cost and the increased burden to environment while undertaking any infrastructural projects. In this paper, recycling of waste tires and disaster mitigation in the context of Japanese experiences were focused, and few geo-disaster reduction techniques developed in Japan using TDGM are described.

Geo Construction Techniques for Hazards Mitigations Using TDGM

Quay Wall Protection During Earthquake Using Vertical Inclusion

During the 1995 Hyogo-ken Nanbu Earthquake, Japan many waterfront retaining walls were reported to be tilted in the seaward direction, while soil liquefaction was also observed in the backfill soil (Inagaki *et al.*, 1996). A technique to protect retaining wall from such damage was developed and validated through experimental investigations, which were reported in Hazarika *et al.* (2008) and Hazarika *et al.* (2010).

Description of the technique

The technique, named SAFETY (Structural Stability and Flexibility during Earthquakes using Tires), consists of a compressible inclusion made of tire chips, which was placed as a cushion behind the retaining wall as can be seen in Fig. 2. The purpose of the installation of such cushion behind the quay wall was to absorb the impact due to an earthquake, and at the same time restricting the displacement of structures.

However, in order to optimize the amount of tire chips to be used in making the cushion, some percentage of sand or gravel can be mixed with tire chips by enclosing the mixture inside geotextile bags, and then placing those behind the structure. This kind of mixing and confining technique saves the amount of tire chips/tire shreds to be used in a project. At the same time, it also reduces any unwanted vertical settlement due to vertical load coming from the structure on the backfill, since tire derived materials have high compressibility. In addition, mixing and confining of the materials before placing makes the execution easier and faster.

In the backfills of waterfront retaining structures, which are susceptible to liquefaction, vertical drain installation in the backfill was proposed (Hazarika, 2012). Vertical reinforcing inclusion, thus, refers to the cushion and vertical drains which are made of highly permeable tire chips, and are placed vertically as part of backfill material. The vertical drains can quickly dissipate the generated excess pore water pressure during earthquake. The schematic diagram of SAFETY technique is shown in Fig. 3. The drains

Fig. 4 Models used in the shaking table experiment.

can also be made of mixtures of tire chips and gravel in an optimum mixing percentage, as both the materials possess almost similar permeability.

Test cases and test procedures

Experimental verification of the technique described above, was made by conducting 1 g shaking table test using the large three-dimensional underwater shaking table assembly belonging to the Port and Airport Research Institute (PARI), Japan. The circular shaking table of diameter 5.65 m is mounted on a 15 m long, 15 m wide and 2 m deep water pool. Details of the shaking table assembly and the model construction procedures used in this study can be found in Hazarika *et al.* (2008) and Sugano *et al.* (1996).

A caisson type quay wall was used in this testing, which were placed in a soil box of 4 m long, 1.25 m wide and 1.5 m deep. Four different models were constructed in which each of the models differs on the selection of backfill material as shown in Fig. 4. In Case 1A, a conventional caisson with gravel as part of the backfill was used. In Case 1B, the entire gravel backfill was substituted by tire chips. A layer of gravel was placed on top of the tire chips to prevent any uplifting of tire chips during earthquake due to their low weight. Case 2A is the case in which the top half of the gravel in Case 1A was replaced by tire chips. In Case 2B, a compressible inclusion and a series of vertical drains made of tire chips were installed as part of the backfill as explained in Fig. 3 in the section above. A total of 23 vertical drains of diameter 50 mm were installed with a spacing of 210–250 mm in triangular pattern. To ensure proper water drainage during earthquake loading, on top of the entire drains a 50 mm thick gravel layer underlying a 50 mm thick soil cover was laid. This later also could prevent any uplifting of the tire chips drain. A cross sectional view of this case and the instrumentations of the testing program are shown in Fig. 5.

The test models consist of 0.1 m thick bedrock layer, 0.45 m thick dense seabed layer (relative density of 78.59%), 0.1 m thick foundation rubble and 0.85 m thick backfill soil (relative density of 45.95%). Saturation of the backfill was achieved by elevating the water level up to 1.3 m at a slow rate, after constructing and instrumenting the models.

Scaling law for model to prototype ratio of 1/10 was selected in this study. The similitude of various parameters in 1 g gravitational field were calculated based on the soil-structure-fluid system proposed by lai (1989). The test models shown in Fig. 4 were subjected to an actual earthquake loading (the N-S component of the strong motion acceleration record at the Port Island, Kobe, Japan during the 1995 Hyogo-ken Nanbu Earthquake).

Test results

Fig. 6 shows the time histories of horizontal displacement experienced by the caisson during the test duration at the top (D2) and bottom (D1) of the caisson. Negative signs of the horizontal displacement indicate that the displacement was towards the sea. It can be seen that the residual displacement of the retaining wall with conventional backfill (Case 1A) was 9.1 mm and 7.8 mm at the top and the toe respectively. Replacing the rubble backfill with tire chips (Case 1B) helps reducing the amount of residual displacement by almost 50% where the displacements recorded were 4 mm and 3.3 mm at the same points. The combination of tire chips and rubble as backfill material (Case 2A) also shows some reduction in the residual horizontal displacement compared to the conventional case. The vertical inclusion technique (Case 2B), yields similar residual horizontal displacement as in the case of Case 1B.

Fig. 7 shows the dissipation capabilities of the excess pore water pressures (EPWP) generated during earthquake, due to the installed drains. Sustained and non-dissipative excess pore water pressures lead to the liquefaction of loose sandy soils. As can be

Fig. 5 Cross section and instrumentations of the models used in the experiment. All dimensions are in mm.

seen in this figure, In Case 1A (conventional backfill), the EPWP is continuously increasing and sustaining in that state for a longer duration, indicating the backfill liquefied. Case 1B also shows the same trend. However, Case 1C and 1D in which tire chips and gravel tire chips were used as drainage enhancing materials, the dissipation is faster, thus could prevent any liquefaction in the backfill.

Tsunami Protection of Sea Wall Using Whole Tires

Many sea walls were damaged during the 2011 off the Pacific Coast of Tohoku Earthquake and resulting tsunami. Examples of failures of many seawalls and breakwaters during that disaster are reported in [Hazarika et al. \(2012a\)](#). Any countermeasures, to protect seawalls from future damage during tsunami, require the knowledge of damage mechanism of seawalls due to tsunami. When incoming tsunami overflows the seawall, it collides with the seawall foundation, and due to rapid overflow, seawall embankment is scoured due to the impact of water resulting in outflow of the concrete panel covering of embankment. On the other hand, when the tsunami returns to sea (backrush), the force of backrush hits the sea wall with a huge impact force, and as a result seawall collapses completely due to reduced strength of the foundation and the structure. Therefore, to protect seawall from damage due to tsunami, we need to adopt two countermeasures simultaneously: (a) protection of soils behind the seawall due to tsunami impact force and (b) protection of concrete cover behind the seawall due to force of backrush. A countermeasure, taking into the account the above two factors, is described below.

Description of the technique

To protect seawall from impact force of tsunami, a new concept of using waste tire (a resilient material) structures behind seawall was developed ([Hazarika and Fukumoto, 2016](#)), which is shown in [Fig. 8](#). Considering the esthetic, suitable plants can be planted within the tires to preserve the greenery ([Hazarika et al., 2016](#)).

To evaluate the tsunami impact force absorption and the load dispersion effect of the protective tire structures explained in [Fig. 8](#), Tsunami Overflow Tests (TOT) were conducted by placing model tires behind the seawall in various configurations and different filling conditions of tires.

Test model and test conditions

A new apparatus for TOT was developed by the research group of adaptation to global geo-disaster and environment at Kyushu University. In this apparatus, a model soil box made of acryl (1200 mm in length, 300 mm in width and 1000 mm in height) was used to reproduce the overflow phenomenon of tsunami. The schematic diagram of the apparatus developed in this research is

Fig. 6 Comparison of the horizontal displacements of the caissons (a) At the top of the caisson (D2 of Fig. 5) (b) At the bottom of the caisson (D1 of Fig. 5).

shown in Fig. 9. The model seawall (height 60 cm and crown width 12 cm) is placed inside the soil box. There is a hinge gate above the model seawall that stores water and can reproduce the overflow phenomenon of tsunami.

It was expected that the ability of tires to reduce the impact force of tsunami, will be different according to the number of tire layers, types of filling material and style of tire placing (configurations). Therefore, the following test cases were examined as explained in Fig. 10. Vertically laying cases (Case 2: two layers, Case 3: three layers) and alternately laying case (Case 5: slopped three layers). Three different filling conditions of tire were examined: (1) Hollow tire (without any filling) (2) Tire filled with Masado (decomposed granite soils abundant in Kyushu area, Japan) and (3) Tire filled with tire chips (TC) of maximum grain size 2 mm.

In the tests, model tires with outer diameter 85 mm, inner diameter 45 mm and thickness 21 mm were used instead of actual tires. There are five load tables (Table 1–5) in the landside of the apparatus shown in Fig. 9. Each load tables are supported with two load cells as shown in the figure. In the data analysis of this test, average value of the two load cells (in each table) was taken, and then the maximum of those average values was determined.

Test results

Fig. 11 shows the calculated values of the water impact force against the time of overflow. Two typical cases are shown in the figure. One with no tire placed on the back of sea wall and the other is the case of sea wall reinforced by slopped 3 layers of tires (Case 5 of Fig. 10). Comparison of the results shows that there is a considerable reduction (more than one third) of the impact force due to tire placement.

Fig. 7 State of the pore pressure dissipation with time in the four cases (a) W13 (Backfill bottom) (b) W14 (Mid-height of the backfill) (c) W15 (Top of the backfill).

Comparisons were also made for the magnitude of impact force for different filling conditions of tires, as indicated in Fig. 12. This figure shows the variation of impact loads due to Case 5 (three layered slope arrangement) for the different filling conditions. It can be observed that, the impact force is reduced when the model tires are introduced behind the seawall in all the filling conditions of tires. This figure indicates that the impact force is reduced to some extent when hollow tires (without any filling materials) are placed behind the seawall. The impact force is further reduced when the tire chips-filled or the soil-filled model tires are used. In addition, the reduction is faster (time taken to reach the steady state is smaller) in these two cases (filled tires). The

Fig. 8 Protection of sea wall by using whole tires. Modified from Hazarika, H., Fukumoto, Y., 2016. Sustainable solution for seawall protection against tsunami-induced damage. *International Journal of Geomechanics* 16, C4016005.

Fig. 9 Tsunami overflow testing (TOT) apparatus. Modified from Hazarika, H., Fukumoto, Y., 2016. Sustainable solution for seawall protection against tsunami-induced damage. *International Journal of Geomechanics* 16, C4016005.

Fig. 10 Test Cases (a) Case 2 (Vertically placed two layers) (b) Case 3 (Vertically placed three layers) (c) Case 5 (Slopped three layers).

reduction percentage is found to be different depending on the filling materials of the tires. Tires filled with soils lead to the significant decrease of the impact load as compared to tires filled with pure tire chips. Therefore, it can be said that, instead of using pure tire chips, mixing tire chips with soils can be a viable alternative when applying the technique in actual field conditions.

From esthetic point of view, filled tires on the back of a seawall is not appealing. Therefore, cultivation of suitable plants inside actual tires (used passenger car tire) was done in field using a yard inside the Ito campus of Kyushu University. Field test shows that the greening effect could be maintained in all the seasons in a year by appropriate selection and plantation inside the tires. The details of those field tests can be found in [Hazarika et al. \(2016\)](#).

Protection of Residential Building During Earthquake Using Horizontal Inclusion

According to the Ministry of Land, Infrastructure, Transport and Tourism, Japan (MILT, 2015), nearly 27,000 houses were damaged owing to liquefaction due the 2011 Off the Pacific Coast of Tohoku earthquake, about half of which were located in the Tokyo Bay area. Liquefaction occurred widely along the Tokyo Bay area, owing to high underground water levels and reclaimed land filled with loose sandy soils (Yasuda *et al.*, 2012). Similarly, a large number of residential buildings in Kumamoto prefecture suffered from liquefaction induced damage by the 2016 Kumamoto earthquake (Hazarika *et al.*, 2017). Severe damage to buildings resulting from liquefaction due to past earthquakes has demonstrated the importance of prevention measures to protect buildings and infrastructure by minimizing ground settlement and lateral spreading.

Description of the technique

To prevent vibration-induced as well as liquefaction-induced damage of residential buildings during earthquakes, it is important to adopt low cost ground improvement technique, since house owners cannot afford to go for the expensive ground improvement techniques applied in conventional infrastructural projects (Hazarika and Nakazawa, 2018). One such low cost technique was developed by Hazarika *et al.* (2009), and later modified as shown in Fig. 13. The modified technique utilizes tire chips mixed gravel under the foundation of residential housing.

Horizontal inclusion, thus, refers to a layer made of tire chips and gravel which are placed horizontally as shown. Mixture of gravel and tire chips layers along with geogrid reinforcement (if necessary) provide sufficient bearing capacity to the foundation that otherwise has to rest on highly compressible tire chips layer.

1 g shaking table test

A series of 1 g model shaking table tests were performed, using the shaking table assembly of Kyushu University, to evaluate the technique described in Fig. 13. The test model (prototype to model ratio of 20) is shown in Fig. 14. Model test box was 600 mm in length, 300 mm in width and 500 mm in height. Toyoura sand was used as foundation soils of a model house. Pure tire chips (2 mm in size) or tire chips mixed gravel (grain size identical to tire chips) were used as the horizontal inclusion. Adjusting the height of the ground in the soil box up to 300 mm, the relative density of base layer and the layer containing horizontal inclusion

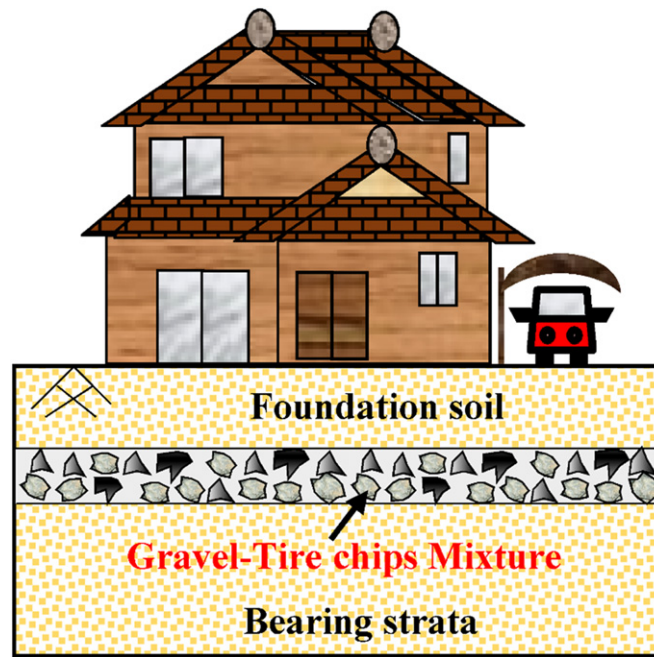

Fig. 13 Protection of residential building using horizontal inclusion.

Fig. 14 Model for 1 g shaking table test.

was adjusted to be around 50%. The layer immediately below the foundation was made of gravel, which represents the top layer of foundation with some sort of soil improvement.

A total of 7 test cases were examined under three different conditions of the horizontal inclusion, which are shown in [Table 1](#). In the Table, Case 0 represents the conventional foundation soil. Case 1, Case 2-1 and Case 2-2 represent the cases in which the thickness of horizontal inclusion was 10 cm. Case 3-1 and Case 3-2 represent the conditions in which the thickness of horizontal inclusion was reduced to 5 cm. Finally, in Case 4, the reinforced layer was located between the upper and lower sand layers. In the table TC refers to tire chips and gf (gravel fraction) refers to the percentage of gravel in the mixture by volume. 30%, 50% and 70% gravel fractions (gf) were used in the tests.

A sinusoidal acceleration of 300 Gal with 3 Hz frequency was imparted into the model for 45 s, and the responses were measured using the LVDT, accelerometers and pore water transducers, which were installed at various locations within the foundation soils shown in [Fig. 14](#).

Table 1 Different configurations of the model test

Depth (mm)	Case 0	Case 1	Case 2-1	Case 2-2	Case 3-1	Case 3-2	Case 4
50	Gravel	Gravel	Gravel	Gravel	Gravel	Gravel	Gravel
100	Sand	Pure TC	TC + gravel (Gf = 50%)	TC + gravel (Gf = 30%)	TC + gravel (Gf = 50%)	TC + gravel (Gf = 70%)	Pure sand
150							
200		Sand	Sand	Sand	Sand	Sand	TC + gravel
250							Sand
300							

**Fig. 15** Liquefaction potentials of the foundation in each case.**Fig. 16** Comparisons of the settlement of model house in each case.

Test results

The maximum of excess pore water pressure ratios at various depths within the foundation soils are shown in Fig. 15. In the unreinforced foundation (Case 0) the excess pore water pressure exceeds 1.0 at all the depths indicating liquefaction in the foundation soils. Except for Case 4, in all the other cases the liquefaction was restrained in the reinforced layer. While Case 2-1 is the most effective in restraining liquefaction, Case 2-2 and Case 3-2 also display no liquefaction in all throughout the depth. These results imply that when the thickness of reinforced layer is 10 cm, liquefaction can be prevented using the proposed horizontal inclusion technique. However, when the layer thickness is reduced to 5 cm, the gravel fraction has to be over 70% to ensure its function. This may be attributed to the light weight nature of tire chips, which may not be able to exert sufficient overburden pressure on the layers underneath.

The average final settlements of the model house due to the cyclic loading for each case are shown in Fig. 16. From this figure it is clear that the settlement of the house reinforced by pure tire chips (10 cm thick inclusion) can be reduced to half that of the

Fig. 17 Grain size distribution of gravel and tire chips.

non-reinforced foundation. However, when comparing with the gravel mixed tire chips reinforced foundation (10 cm thick inclusion), it can be observed that the settlement of the house was reduced further to half as compared to the foundation reinforced with pure tire chips. This implies that mixing gravel to tire chips can decrease the differential settlement due to enhanced bearing capacity.

In addition, the settlement decreases with the increase in the thickness of reinforced layer and the amount of gravel fraction. Furthermore, Case 2-1, in which the reinforced layer thickness was 10 cm and gravel fraction was 50%, the settlement is significantly less. In Case 4, the settlement was found to be even larger than the unreinforced foundation. This implies that this particular pattern of reinforcement is not appropriate for the model considered in this study. In other words, the location and thickness of the horizontal inclusion are also important design consideration in this technique.

Dynamic Properties of Gravel and Tire Chips Mixtures

Evaluation of dynamic behavior of gravel-tire chips mixture (GTCM) is necessary to firmly establish the techniques described above. Therefore, to investigate the influence of gravel fraction on dynamic properties as well as liquefaction resistance of GTCM, a series of stress controlled consolidated undrained cyclic triaxial tests were conducted on GTCM with different gravel fractions.

Test Materials and Procedures

Fig. 17 demonstrates the particle size distribution of gravel and tire chips (TC) used in this study. Other physical characteristics of materials such as maximum diameter of gravel and tire chips particles (D_{max}), coefficient of curvature (U_c), coefficient of uniformity ($U_{\dot{c}}$) are also displayed in **Fig. 17**. The maximum grains size of TC and gravel were limited to less than 1/6 of specimen diameter to avoid the effect of sample size on the results of experiments. According to the Japanese Geotechnical Society Standard (JGS 0131), this type of gravel is classified as poorly graded (SP). The specific gravities (G_s) of gravel and TC were determined as per the Japanese Geotechnical Society (JGS 0111) recommendations, and they were found to be 2.81 and 1.17 for gravel and TC respectively.

In order to have homogenous samples, the under-compaction method was used for the preparation of specimens (Ladd, 1978; Pasha *et al.*, 2019). Mixtures of desired relative densities were obtained by mixing manually and carefully, placed into the mold and compacted in 10 layers. Samples were saturated by allowing de-aired water to flow through from bottom of the sample. The back-pressure technique was adopted to enhance the degree of saturation of samples. Full saturation was assumed to be achieved when Skempton's B parameter ($\Delta u / \Delta \sigma_3$) was greater than 0.95. An isotropic consolidation pressure was applied to samples, while maintaining constant initial backpressure (200 kN/m²). Samples were consolidated to the effective confining pressure of 50 kN/m² and 100 kN/m². Stress-controlled undrained cyclic triaxial tests were conducted at a constant frequency of 0.1 Hz, relative density of 50% and different cyclic stress ratios ($\sigma_d / 2\dot{\sigma}_{3c}$).

Test Results

Typical results (stress paths) on cyclic behavior of GTCM at stress ratio ($\sigma_d / 2\dot{\sigma}_{3c}$) of 0.3 with different gravel fractions for relative density of $Dr = 50\%$ and confining pressure of $\dot{\sigma}_{3c} = 100$ kPa are shown in **Fig. 18**. As is evident, the effective mean stress ($\dot{p}$) decreases with cyclic deviator stress (q), however, none of the GTCM samples did reach the state of zero mean effective stress at the conclusion of cyclic loading. The decrease in the effective mean stress ($\dot{p}$) occurs due to the rapid generation of excess pore water pressure during cyclic loading. Furthermore, mechanism of the failure for GTCM with $Gf = 100\%$ and $Gf = 87\%$ is similar to that

Fig. 18 Cyclic effective stress paths of GTCM at $\sigma_d/2\sigma_{3c} = 0.3$, $D_r = 50\%$ and $\sigma_{3c} = 100$ kN/m²: (a) $G_f = 100\%$; (b) $G_f = 87\%$; (c) $G_f = 44\%$; (d) $G_f = 30\%$.

of flow type failure in which the samples exhibit combination of contractive and dilative behavior. The samples underwent excessive deformation leading to complete loss of shear strength due to the rapid building up of excessive pore water pressure during the cyclic loadings. For the GTCM samples with $G_f = 44\%$ and $G_f = 30\%$ similar mechanism to that of cyclic mobility type of failure is observed.

The effect of confining pressure on the pore water generation of GTCM with $G_f = 30\%$ and $D_r = 50\%$ at $(\sigma_d/2\sigma_{3c})$ of 0.35 is shown [Fig. 19](#). The GTCM samples exhibit higher liquefaction resistance even at low confining pressure. This behavior is similar to that of denser sand samples at higher confining pressure. The reduction in effective confining pressure remarkably enhances liquefaction resistance of representative GTCM samples with $G_f = 30\%$. This might be caused due to the reduction in the hydraulic conductivity of mixture with the effective confining pressure ([Edil and Bosscher, 1994](#)).

In [Fig. 20](#), for a given number of cycles ($N_l = 20$), the maximum of excess pore water ratio ($R_u = u/\sigma_{3c}$) of GTCM samples with relative density of $D_r = 50\%$ is plotted at stress ratio $(\sigma_d/2\sigma_{3c}) = 0.3$ and confining pressure of $\sigma_{3c} = 100$ kN/m² for different G_f . It can be seen that liquefaction resistance decreases with decreasing gravel fraction from 100% to 87% and then increases with further decrease in gravel fraction. Possibly, in GTCM with $G_f = 100\%$ (pure gravel) the soil sample is in medium dense state and exhibits relatively high dilative behavior resulting in high liquefaction resistance. When small amount of tire chips is added to the mixture, GTCM matrix is still formed by gravel particles. However, some of the solid gravel particles are replaced by soft tire chips particles with relatively low stiffness. Presence of those soft tire chips inclusions in the voids of the mixture, GTCM sample with $G_f = 87\%$ shows gravel like behavior in relatively loose state, which results in relatively low liquefaction resistance in comparison to that of $G_f = 100\%$. Optimum value of gravel fraction in which GTCM sample shows remarkable improvement in liquefaction resistance of mixture was around 50%.

The shear modulus variations of GTCM samples with different $G_f(\%)$ are shown in [Fig. 21](#). For the GTCM specimens with $G_f = 100\%$ and $G_f = 87\%$ shear modulus decreased drastically with the shear strain within the few cycles of loading. This

Fig. 19 The effect of effective confining pressure on the evolution of excess pore water ratio of GTCM against number of stress cycles (N) at $G_f = 30\%$ and $\sigma_d / 2\dot{\sigma}_{3c} = 0.35$ (a) $\dot{\sigma}_{3c} = 50 \text{ kN/m}^2$ $\dot{\sigma}_3 = 100 \text{ kN/m}^2$; (b) $\dot{\sigma}_{3c} = 100 \text{ kN/m}^2$.

Fig. 20 Maximum excess pore water ratio of GTCM with different $G_f(\%)$ at Cyclic Stress ratio $\sigma_d / 2\dot{\sigma}_{3c} = 0.3$, $\dot{\sigma}_{3c} = 100 \text{ kN/m}^2$ and number of cycles ($N = 20$).

Fig. 21 Effect of gravel fraction on shear modulus of GTCM: (a) $30\% \leq G_f \leq 100\%$ (b) $30\% \leq G_f \leq 55\%$.

Fig. 22 Evolution of damping ratio with shear strain for GTCM specimens.

reduction in shear modulus with an increase in shear strain can be attributed to the decrease in the gravel inter-particle contact after rapid development of pore water pressure during the cyclic loading. Tire chips content did not significantly affect the shear modulus of specimen for $G_f = 55\%$, 44% and 30% and shear modulus of specimens at higher shear strains are almost identical. This is probably because gravel inter-particle contacts are minimal (especially at very high shear strains $> 1\%$) where GTCM matrix is mainly formed by tire chips particle with relatively low stiffness in comparison to that of gravel particles.

Evolution of damping ratio of GTCM mixtures with shear strain is shown in Fig. 22. Damping ratio slightly increases with decreasing gravel fraction in mixture. The reduction in damping ratio value with shear strain may occur due to the rapid development of pore water pressure during cyclic loadings. Inter-particle contacts significantly decrease with pore water pressure, which results in a reduction of frictional energy loss in soil skeleton with the number of cycles.

Conclusions

The following are the some of the main conclusions of this research.

- (1) The use of pure tire chips or in combination with gravel as part of the backfill of retaining structure improves the performance of the structure during an earthquake.
- (2) Significant lowering of the pore water pressure build up within the backfill could be achieved in the case of backfill improved by vertical inclusion technique.
- (3) The tsunami impact force behind sea walls can be reduced considerably by placing filled whole tires (with a suitable filling material) to protect the damage of such structures from impact force and resulting scouring and erosion.
- (4) Tires must be filled with soils (or with other materials) to provide certain stiffness, so that they should be able to absorb the impact force of tsunami.
- (5) In the case of horizontal inclusion technique, tire chips was found to be an excellent liquefaction mitigating material, However, due to its' light weight nature, it may also cause unexpected settlement of the structure. When the reinforced layer is mixed with gravel, the shear stiffness in reinforced layer will be increased, and thus the settlement will be reduced.
- (6) When the thickness of reinforced layer is 10 cm (2 m in prototype) and gravel fraction is 50%, the technique yields the best performance, as the rise of excess pore water pressure could be significantly restrained. This ultimately leads to the reduction of earthquake induced settlement of the structure.
- (7) When the thickness of horizontal inclusion is 10 cm (2 m in prototype) and gravel fraction is 50%, the liquefaction mitigation technique yields the best performance, as the rise of excess pore water pressure could be significantly restrained. This ultimately leads to the reduction of earthquake induced settlement of the structure.
- (8) Two behavioral zone (gravel like and gravel-tire chips like behavior) of GTCM can be used to explain the liquefaction potential as well as dynamic behavior of GTCM specimens.
- (9) Liquefaction resistance of GTCM specimens are remarkably influenced by gravel fraction in mixture. For the higher gravel fractions ($G_f > 87\%$), soil matrix are mainly formed by gravel, and thus, adding small amount of tire chips decreases the liquefaction resistance due to reduction in gravel inter-particle contacts during loading. However, for $G_f < 87\%$, liquefaction resistance increases with a decrease of gravel fraction in the mixture. This is because the mixture tends to exhibits gravel-tire chips like behavior or tire chips like behavior (non-liquefiable materials).
- (10) Gravel fraction plays an important role in the dynamic behavior and liquefaction resistance of the GTCM. 50%–60% is the best mixing percentage, in which the rise of excess pore water pressure could be significantly restrained without compromising the stiffness of the reinforcing inclusion.

Application of the geo-disaster mitigation techniques discussed here, is expected to contribute towards reducing the global warming by cutting down the release of greenhouse gas through recycling of waste tires, and thus, could be an effective adaptation measure against climate change. The techniques also possess tremendous potentials for adopting in developing and emerging economies, where alarming rate of car usage as the mode of commuting are already creating problems of stockpiling and illegal dumping, which in turn are placing a huge burden on our environment. Through a judicious decision during design process, if the cost reduction can be additionally achieved through use of such materials in geotechnical constructions, establishment of groundbreaking adaptive technology will not be a distant dream.

To implement the technique, prototype testing using centrifuge model test, and numerical simulation using the material behavior described in this paper will be essential. Mapping of constitutive relationship of the material using Artificial Intelligence (Pasha *et al.*, 2018) could be a useful tool in that direction.

Introduction

Carbon nanotubes (CNTs) are made of hexagonal carbon rings in the form of cylindrical carbon molecules with nanometer-sized diameter and micrometer-sized length (where the length to diameter ratio exceeds 1000). The structure is made of enrolled cylindrical graphitic sheet (called graphene) rolled up into a seamless cylinder with diameter of the order of a nanometer. This one-dimensional material having different chirality is dependent on the position of the carbon atoms. There are two types of CNTs: Single wall carbon nanotubes (SWCNTs) and multiwalled carbon nanotubes (MWCNTs).

Currently, many studies have used waste materials for various potential applications. As for MWCNTs, there is a number of carbon sources from waste materials such as waste vegetable/animal oil, industrial waste, and waste plastics (Deng *et al.*, 2016). Cooking palm oil, which belongs to the vegetable waste group, is widely used in the consumer food chain and has escalated due to small to medium enterprise ventures in the food and beverages manufacturing industry recently. The dumping of cooking palm oil waste has triggered a major concern over its effect on the environment in terms of the stability of ecosystem, biodiversity, and pollution of Earth. In this article, we look at the beneficial use of waste cooking oil as the starting material for the synthesis of CNTs. It will be synthesized via modified chemical vapor deposition (CVD) method by using the injection of waste cooking oil as the carbon source and mill-scale waste (Fe_3O_4) as the catalyst. This interesting method is even more convenient compared with other previous CVD method as reported in MWCNTs synthesis studies (Ahmad *et al.*, 2013; Baddour *et al.*, 2008; Bhatia and Prasad, 2010; Kumar and Ando, 2010; Tripathi *et al.*, 2017). CNTs exhibit a great range of remarkable properties, including unique mechanical and electrical characteristics. These remarkable properties have led to the use of CNTs as microstrip patch antenna (MPA) in the past few years.

Recycling of Waste Materials Into Carbon Nanostructures

A key part in the production of CNTs is the carbon source and catalyst. The types of carbon source would greatly influence the morphological structure of the end product due to not only providing the carbon atoms, but also affecting the growth of the CNTs. Meanwhile the catalyst also plays the role of affecting the morphological structure and yield of CNTs synthesized. Conventional carbon sources such as ethylene, benzene, acetylene, and methane are widely used. These carbon sources however are also required by many other industries for other applications. It is of great importance to develop new abundant cost-saving carbon sources for the synthesis of CNTs. Other carbon sources from waste materials are tabulated in Table 1.

Many types of catalyst were used in the synthesis process of CNTs (Table 1), however recycling of waste materials as catalyst is not widely reported. This article describes a method on using mill-scale waste as a catalyst for synthesis of CNTs via CVD method. Mill-scale waste is a porous, hard, and brittle coating of several distinct layers of iron oxides (predominantly Fe_3O_4) formed during the fabrication of steel structures from steel mills. It is magnetic in nature with iron content up to as high as 93%. Most of the steel mill-scale waste (almost 80%) end ups in a landfill; a small fraction of it is also used to make reinforced concrete.

Application of Carbon Nanotube in Microstrip Patch Antenna

MPA consists of a thin metallic patch kept on dielectric substrate, and below the dielectric substrate there is a conducting ground plane as shown in Fig. 1. Previous studies have embarked on the usage of carbon fiber composites such as CNTs, which has caught the interest of many researchers in the attempt to replace metals in antenna. This article intends to present the application of CNTs made of waste cooking oil as a patch antenna and discuss the design and fabrication of these structures and the properties of the acquired antenna.

The theory of fundamental transmitting properties of SWCNTs as dipole antennas has been explored by Hanson (2005), with a 10- μm -long CNT serving as a dipole antenna. However, it is still considered a short dipole antenna compared with free-space wavelength, and in reality it is still very difficult to obtain a few centimeter lengths of CNTs. Therefore, recently the focus has been switched to producing CNT-based patch antenna, which can be fabricated using multiple methods, as well as possibility of utilizing the antenna in flexible environment. Keller and Zaghoul (2011) demonstrated a simulation of meshed CNT threads for patch antenna, of which conducting CNT threads and semiconducting CNT threads were interwoven to serve both as conductive

Table 1 Hydrocarbon sources from waste materials for synthesis of CNT

Hydrocarbon source	Catalyst	Method	Synthesis temperature (°C)	Morphology of carbon nanostructures	Raman ID/IG ratio	Refs.
Tube plastic waste made of polypropylene	Stainless steel 316 (SS 316) metal tube (acted as both reactor vessel and catalyst)	Two-stage self-catalytic chemical vapor deposition (CVD) reactor	900	Multiwalled carbon nanotubes	0.48	(Tripathi <i>et al.</i> , 2017)

Fig. 2 Copper- and carbon nanotube (CNT)-sheet-based microstrip patch antenna. Reproduced from Keller, S.D., Zaghloul, A.I., Shanov, V., *et al.*, 2014. Radiation performance of polarization selective carbon nanotube sheet patch antennas. *IEEE Transactions on Antennas and Propagation* 62 (1), 48–55.

patch for antenna, and also as the dielectric resonator for gas sensing. Later, Keller *et al.* (2014) successfully fabricated a CNT sheet antenna with different sheet thickness giving impact to the radiation performance of the MPA itself (Fig. 2). The CNT sheet was sandwiched between Kapton tape, which served as adhesive tape on one side and protection film on the other side. CNT sheet with higher thickness value exhibited better reflection coefficient and gain as compared with lower ones, however the thickness is still below the skin depth of the material as compared with the copper patch, which is around 17 μm , which leads to performance reduction overall.

Meanwhile, Elwi *et al.* (2010) demonstrated a MWCNT-based patch antenna using inkjet printing method, of which the CNTs were added to a sodium cholate solution to produce a MWCNT ink with concentration of 5 mg/l and then was filled into inkjet cartridge for printing purpose (Fig. 3). The results exhibited improved bandwidth for MWCNT-based MPA as compared with MPA using copper patch; however the gain is lower than copper-based MPA due to low conductivity of the MWCNT ink. It is noted that the radiation patterns remained unchanged.

Another approach to incorporating CNTs to MPA structure (Fig. 4) is by mixing or doping CNTs with conductive polymer, such as polyaniline (PANI), as demonstrated by Hamouda *et al.* (2014). The PANI/CNT composite was fabricated onto Rogers RT/Duroid 5870 substrate, with the composite having three different thickness of 50, 70, and 110 μm to study the effect on the performance of MPA. The results showed improvements in terms of bandwidth, but reduction in the return loss. Further improvement can be realized in the conductivity of the PANI/CNT composite can be further increased.

In summary, the use of CNTs as conductive materials for fabrication of MPA has proven to give good results, although the conductivity of the composite can be further increased, hence can be compared with copper-based MPA. The method in CNT

patch antenna can also be studied, of which this work aims to study the method of producing CNT patch antenna using thick film technology that utilizes a screen printing process. The CNT paste can be mixed with an organic vehicle with suitable ratio, therefore the CNTs volume can be increased and subsequently increase the conductivity of the CNT patch when it is fabricated.

Experimental Synthesis of Carbon Nanotubes From Waste Cooking Oil for Microstrip Patch Antenna

The methodology of the research work is divided into three stages: (1) synthesis of MWCNTs, (2) CNT thick film paste preparation, and (3) MPA fabrication. Some results from the above research work are also discussed.

Synthesis of Multiwalled Carbon Nanotubes

The starting raw powder materials of millscale (Fe_3O_4) waste were milled using a Spex8000D milling machine with a ball to powder ratio of 10:1 for 6 h to obtain nanosized particles. The milled mill-scale powder or iron oxide nanoparticles were used and acted as a catalyst to synthesize MWCNTs via CVD method. An alumina boat containing approximately 0.5 g milled powder was placed at the center of the furnace and was flushed with argon at 100 sccm. Then, the furnace was heated at different synthesis temperature (ST) of 650°C, 750°C, and 850°C. Once the furnace reached the targeted ST, the filtered waste cooking oil was injected with constant flow of 10 ml/H with a syringe pump into the alumina ceramic tube containing the catalyst under an argon gas flow. The furnace was cooled down to room temperature before the sample was extracted for analysis. The setup of the CVD method is shown in Fig. 5. The extracted CNTs were then characterized by using field emission scanning electron microscope (FESEM) (FEI Nova NanoSEM 230), energy dispersive X-ray (EDX), high resolution transmission electron microscope (HRTEM), X-ray diffraction (XRD), thermal gravimetric analysis/differential thermal analysis (TGA/DTA) (Mettler Toledo TGA/DSC 1 HT) and Raman spectroscopy (Witec Alpha 300R).

Carbon Nanotube Thick Film Paste Preparation

An organic vehicle or binder was used in the paste preparation process. It was prepared by mixing 85 wt% linseed oil (CAS no. 67746-08-1, Daler Rowney) with 12.5 wt% m-xylene (CAS no. 108-38-3, Sigma-Aldrich USA, ReagentPlus grade, 99% assay) using magnetic stirrer at 250 rpm for 3 h, and later 2.5 wt% α -terpineol (CAS no. 10482-56-1, Sigma-Aldrich USA, natural, $\geq 96\%$ assay) was added to the mixture. Next, the mixture was continually stirred for another 2 h with temperature kept at 40°C (Abadi, 2010). Then, the prepared organic vehicle was added to CNTs with powder to organic vehicle weight ratios of (50:50), and mixed thoroughly using magnetic stirrer for 3 h to obtain a homogenous paste.

Microstrip Patch Antenna Fabrication

Fabrication of MPA was carried out by printing CNT paste onto kapton substrate via screen printing method. Next, the prepared samples were annealed at temperature of 300°C for 30 min in a box furnace. Then, a SubMiniature version A connector was attached by soldering it to the patch antenna. A copper tape was attached behind the patch of kapton substrate as a ground plane. Finally, after fabrication of antenna is completed, the return loss (S_{11}) and resonant frequency of all samples were measured using Vector Network Analyzer (Keysight, PNA 5227A) in the frequency range of 1–8 GHz.

Results and Discussion of Synthesis of Carbon Nanotubes From Waste Cooking Oil for Microstrip Patch Antenna

Fig. 6 shows the micrograph of powder sample milled for 6 h, which has been carried out using scanning electron microscopy. The particle size was found to have an average around ~ 140 nm as can be seen in the particle size distribution (Fig. 7). The agglomerations of the particles, as can be observed, occurred due to magnetic forces of nanoparticles. The particle size distribution

Fig. 5 Experimental setup of chemical vapor deposition method for carbon nanotubes synthesis using mill-scale waste as catalyst.

Fig. 6 Scanning electron microscopy micrograph of resulting particles after 6 h of milling time.

Fig. 7 Particle size distribution of milled mill-scale powders.

Fig. 8 X-ray diffraction pattern of mill-scale milled using high energy ball milling for 6 h.

obtained from FESEM micrograph shows that the size distribution is broad as various particle sizes were obtained during mechanical alloying process. Nanosized particles have high reactivity due to larger surface area and it is one of the most important parameter to be considered for the growth mechanism of CNTs on the surface of millscale (Nershev *et al.*, 2003; Kukovitsky *et al.*, 2002; Helveg *et al.*, 2004; Cheung *et al.*, 2002).

The XRD spectra of mill-scale before and after milling using high energy ball milling at 6 h is shown in **Fig. 8**. The result exhibits the occurrence of magnetite (Fe_3O_4) and wustite (FeO) phases only. This can be obtained by comparing the peaks with the standard reference code data for Fe_3O_4 (01-089-3854) and FeO (01-074-1886). The presence of magnetite can be seen in the plane (113) at $2\theta = 36.33^\circ$ and the presence of wustite (002) and (022) were detected at $2\theta = 42.09^\circ$ and 61.04° respectively.

FESEM images of MWCNTs grown by CVD method at 650°C , 750°C , and 850°C are shown in **Fig. 9(a–c)** respectively. The web-like structure consists of nanotube bundles. The bundling structure results from the attractive van der Waals forces between nanotubes. A group of CNTs can form a randomly oriented CNT mat or super aligned CNT arrays, depending on the density of catalyst and their activities at different synthesis conditions (Devi *et al.*, 2017). External diameters of each sample are 146.3, 133.1, and 99.7 nm for different ST and their size distributions are shown in **Fig. 10**. The growth of MWCNTs were also seen to be tangled

and in a disorderly arrangement. According to the results obtained by Qi *et al.* (2007), CNT-Fe and CNT-Co present a nonlinear growth. It is also common to find the catalyst encapsulated inside the CNTs, as a result of the growing process and the little chemical interaction between catalysts. In this sense, the equilibrium state of iron oxide phases (millscale magnetite) promotes the agglomeration of the catalyst nanoparticles and decreases the encapsulation. The EDX spectrum reveals the presence of iron (Fe), carbon (C), and argentum (Ag) peaks in FESEM view without any other impurities (Fig. 11). The peak of Ag was present in the EDX spectra due to the use of silver paste during sample preparation for putting MWCNT samples on aluminum stub. The fractions of weight percent of CNTs at different ST are listed in Table 2. It was observed that the percentage of carbon content in CNTs was slightly increased as the ST increased as confirmed by EDX analysis.

The FESEM and HRTEM images of as-synthesized MWCNTs in Fig. 9(a–c) reveal the presence of bundles and entanglements with structures mostly straight, spiral, and twisted. However, there is also existence of netlike fibers that were formed by the aggregation of very fine fibers and particle-like carbon [Fig. 9(a)]. One of the reasons for the formation of coiled like structure is due to the regular insertion of pentagon–heptagon pairs at the junction (Dunlap, 1992, 1994).

TGA/DTA can be used to evaluate the thermal stability of a material and characterize the graphitic nature of MWCNTs. Fig. 12 presents TGA/DTA profiles of the as-prepared MWCNTs at a heating rate of 20°C min^{−1} to 1000°C in an atmosphere of air flowing at 50 ml/min^{−1}. For all ST samples, the TGA curves show that the weight loss with thermal degradation at about 481–544°C and decomposed completely at about 716–783°C. It can be found that weight was lost slowly corresponding to the loss of low water content and a few amorphous carbons (Chen *et al.*, 2002). At the temperature range from 480°C to 790°C, the weight decreased sharply indicating that the decomposition of the MWCNTs (Elwi *et al.*, 2010). Also a thing to note is that the curve slope maintained almost the same value from 480°C to 790°C. It is illustrated that the MWCNTs were decomposed at a constant speed, signifying that the CNTs reached to a high purity at 480°C. After 790°C, the weight of the sample remains unchanged. The remainders may be assigned to the metal catalyst used to catalyze the nanotubes, as well as the oxidation products of this catalyst (Chen *et al.*, 2002; Lehman *et al.*, 2011). The figure demonstrates the purity of measured MWCNTs reaching 74.9%, 71.1%, and 77.3% for each respective sample. The primary oxidation temperature for each material is defined as the temperature at the highest peak for the material on the derivative weight curve and can represent the thermal stability of the material (Lehman *et al.*, 2011; Cheng *et al.*, 2011). There is an obviously exothermic peak at 636–650°C for all ST samples, which is attributed to the peak of CNTs.

Raman spectroscopy of MWCNTs yields information about the purity, defects, and graphitic structure and contributes in the distinction presence of MWCNTs relative to other carbonaceous materials. The two dominating peaks present in Raman spectra of MWCNT bundles for all ST samples (Fig. 13) are namely as carbon G (graphite) and D (disorder) band. The D-bands have been attributed to the presence of amorphous carbon due to surface defects of CNTs (Saito *et al.*, 2001) while the G-bands are due to the presence of ordered graphitic CNTs in the prepared samples. The G- and D-band explicitly appears in range ~1575 cm^{−1} and ~1347–1352 cm^{−1} for each sample. The intensity ratio of the two peaks (I_D/I_G), considered a parameter in characterizing the quality of CNTs. The ratio of I_D/I_G was observed to decrease with increase of ST from 650°C to 850°C as shown in Table 3. The lower I_D/I_G value close to zero corresponds to a better degree of graphitization (Wepasnick *et al.*, 2010). The higher I_D/I_G values are influenced by two factors, which are the presence of structural, lattice defect and other carbon materials such as nonuniform nanotubes (Adnan *et al.*, 2015).

Microstrip patch antenna measurement

A rectangular MPA has been designed using transmission line model according to targeted parameter on kapton substrate. The detailed design parameters used are listed in Table 4.

The proposed antenna was examined using a vector network analyzer to determine the S_{11} value of the antenna fabricated using MWCNTs on the kapton substrate. In Fig. 14, the minimum reflection loss (RL) of sample synthesized at 650°C was 12.42 dB at 5.46 GHz. Moreover, for the sample synthesized at 750°C, the minimum RL was 15.97 dB at 3.75 GHz. As for the sample prepared at 850°C, it shows the lowest RL is around 27.82 dB at 3.03 GHz. These results revealed that the

existence of MWCNTs enhanced its electromagnetic (EM)-wave absorption performance. MWCNTs can form conductivity net, and enhance the dielectric loss capability. In addition, the interfacial between magnetite nanoparticles and CNTs enhanced the interfacial polarization capability. The *RL* values reveal that the effect of carbon content in magnetic nanoparticles did play a role to give better absorption properties. Without MWCNTs, only magnetic loss and very weak dielectric

loss work in magnetite nanoparticles to attenuate the EM wave that enters the absorber inside. Raman results revealed that higher ST produced fewer defects and highly graphitic MWCNTs, which in turn improved the conductivity. The increased conductivity due to higher carbon content allows the interfacial polarization and dielectric loss to attenuate the EM wave, which results in the enhanced EM-wave absorption capability of the samples. The microwave energy is conducted by the CNT structures through electron motion, which then generates mobile charges when exposed to EM wave (Elwi *et al.*, 2010). The bandwidth was observed to increase with increasing temperature from 0.76 to 2.03 GHz (Table 5). The MWCNTs are highly current carrying conductive materials where each of the nanotubes in the patch acts as a primary resonator and resonate with electromagnetic waves. Subsequently, current flowing along the edges of the patch induces additional resonances, which enhance the fundamental resonance of the radiating element. Thereby, it will enhance the impedance bandwidth. As explained in Hanson (2006), CNT is usually modeled as an infinite and thin tube-like cylinder formed by a graphene sheet. The impedance of CNTs, z , can be expressed by:

$$z = \frac{1}{2\pi a \sigma d} \quad (1)$$

where a is cross section of CNT radius, σ is material conductivity, and d is CNT wall thickness. Therefore it can be concluded that the role of bulk conductivity and wall thickness of CNTs with thin but finite-thickness tube shape is equal to that of CNT conductance as a whole. Higher conductivity will then lead to lower impedance, thus enhancing current flow of the CNTs.

As a conclusion, MWCNTs were successfully synthesized by using waste cooking oil as a hydrocarbon source via modified CVD. Different characterization techniques were used to investigate the formation of MWCNTs. Raman spectra revealed that I_D/I_G values were decreased as the sintering temperature increased. The decrease of I_D/I_G indicated that the MWCNTs have better graphitization with increasing temperature. Changing the ST can result in better properties of CNTs that would affect the properties of the electron transport in CNTs hence giving better absorption in microwave patch antenna.

This experimental work demonstrated that waste cooking oil, a low-cost and readily available resource, can be used as an inexpensive carbon source for the production of CNTs. Mill-scale waste from the steel factory can also be utilized as catalyst in the CVD process. This article not only describes a new application of waste cooking oil in the field of microwave application, but also offers a solution to the environmental pollution of ecosystems caused by improper cooking oil disposal.

Acknowledgment

The authors thank the students and staff from the Functional Devices Laboratory (FDL) and Materials Synthesis and Characterization Laboratory (MSCL), Institute of Advanced Technology, Universiti Putra Malaysia (UPM) for the support, help, and facilities given throughout the duration of this research. Introduction

The use of vegetable fibers (VF) as a raw material is a return to old civilizations from centuries ago. For instance, 3000 years ago in Egypt, walls were built by reinforcing clay with straw. Recently, a new social awareness has pushed the scientific community to look for suitable solutions for the environment and to reduce the depletion of petroleum resources. Thus, since the second half of the twentieth century, VFs have been extensively used as a suitable reinforcement in many fields of industry (Campilho, 2015). During the last few years, a significant effort has been made by scientists and engineers to provide a technical database for the various types of VF. The reinforcement of polymeric materials with VF as an alternative to conventional synthetic reinforcement can thus become a reality, and also contribute to the increase of the economic value of VF wastes. Furthermore, the production of low cost and eco-friendly composite materials that have some advantages for particular applications such as thermal and acoustic insulation is a very possible concept (Bledzki *et al.*, 2002). The reinvention of natural fibers and the combination of them with polymers has given rise to a new class of materials that can compete with or replace synthetic materials for some structural, but mostly for nonstructural and semi-structural applications.

The introduction of VFs in cementitious matrices began in the 1980s. More recently, housing construction has seen an increase in the application of VF in various non-structural and some structural building components in both exterior and interior applications such as walls, floors, roofing, siding, external cladding, internal lining, building boards, bricks, bracing and fencing. VF composites are also found in the construction of decks and dams, as well as in the building of roads and bridges (Campilho, 2015).

The mechanical behavior of VF reinforced cementitious composites vary according to the origin of the fibers and the type of cementitious matrix. Generally, the utilization of VF in lightweight cementitious composites has shown interesting results due to the compatibility between the fiber and the matrix. Lightweight cementitious materials have mechanical properties close to that of VFs, meaning that they can stop the matrix from breaking the fibers, guarantee a good adhesion and reduce the pullout phenomena of fibers inside the matrix. Furthermore, VF could support the matrix by exhibiting more tensile strength to the lightweight cementitious matrix, which is basically a brittle material, therefore improving the cracking resistance of cementitious materials.

The article reviews the recent research papers which focused on the utilization of VF in the reinforcement of cementitious materials. Firstly, it represents a general overview on the availability of VFs and their properties. Thereafter, the selected mechanical behavior of various types of cementitious materials is summarized.

Short Introduction to Vegetable Fibers

Generality

Natural fibers can be classified according to their origin into animal, mineral and vegetable fibers (VF). The latter one, which are also known as lignocellulosic fibers due to their main components being cellulose, hemicellulose, and lignin (Hakeem *et al.*, 2014) are classified according to their chemical composition as wood and non-wood fibers. Wood fibers have a higher amount of lignin when compared with non-wood fibers, and can be divided into either softwood or hardwood fibers. Softwood fibers can be found in pines, firs, etc., and hardwood fibers are found in birch, eucalyptus, beech, etc. Non-wood fibers cover four major categories according to which part of the plant the fibers are located (e.g., bast, seed, leaf, stalk and reed fibers) (Ardanuy *et al.*, 2015). Fig. 1 shows examples of natural fibers and their classification (based on Jawaid and Abdul Khalil (2011)).

The actual trend of the waste generation process from abundant in nature ago-based materials such as VF has found a wide application in multiple fields of industry, as shown in Table 1 (based on Al-Oqla and Salit (2017)). The annual worldwide production of VF derived from wood and non-wood fibers is presented in Fig. 2, based on the studies of Stokke *et al.* (2013), Väisänen *et al.* (2016) and Al-Oqla and Salit (2017).

The price of VF when compared with the price of synthetic fibers is very low, for example, the price of glass fibers varies between 1200 and 1800 \$/ton, whereas VF costs between 200 and 1000 \$/ton (Satyanarayana *et al.*, 2009; Ardanuy *et al.*, 2015). Moreover,

Fig. 1 Classification of natural fibers.

Table 1 Fields of application and the market of natural fiber composites

<i>Application field</i>	<i>Part in market</i>
Construction and building	15%
Electrical and electronic	4%
Agriculture	3%
Functional	2%
Automotive and transports	16%
Textiles	18%
Consumer goods	18%
Packaging-flexible	9%
Packaging-rigid (incl. food service-ware)	15%
Other	1%

the price of VF varies depending on the available amount and the market demands of these fibers. For instance, the yearly product of date palm and hemp fibers is 4,200,000 tons and 214,000 tons, respectively. This difference in the production ratio makes the date palm fibers 60 times cheaper than hemp fibers, with a price value of about 20\$/ton (Al-Oqla and Salit, 2017). More details concerning the price of some VFs are shown in Fig. 3.

The structure of plant fiber is comparable to a stack of composite folds, whose structure is detailed in Fig. 4 (based on Baley (2005)).

The fiber consists of a primary and a secondary wall, with the secondary wall consisting of the 3 layers S1, S2, and S3. The S2 layer is the thickest one and sets the behavior of the whole fiber. This multilayer structure imparts anisotropy to the material. In a

Fig. 2 Annual production of VF.

Fig. 3 Price of selected VF products.

plant, the fibers are usually assembled in the form of a bundle, which in turn forms their polygonal shapes. The primary and secondary walls contain a frame formed of cellulose microfibrils that is surrounded by a matrix containing hemicellulose and lignin.

The cellulose

Cellulose is a natural polymer and is the most available biopolymer on earth. It can be found in many fields of industry, such as packaging, textiles and paper, as well as being used as a food additive. Cellulose consists of long chains of glucose anhydride unit molecules of up to 15,000 molecules. The glucose anhydride particles are linked together by beta bonds [$\beta(1,4)$]. The cellulose molecule has a linear formation due to this bonding configuration (see Fig. 5). The degree of polymerization (d.p) determined by scientists, which is based on counting the glucan residues, is about 10,000 for wood cellulose (Stokke *et al.*, 2013).

The cell unit form of cellulose is known in literature by different names, such as microfibrils, elementary fibrils, and protofibrils. Such a configuration of different cellulose components is shown in Fig. 6 (based on Al-Oqla and Salit (2017)).

Fig. 4 (a) Complete structure of hemp fiber in a bundle. (b) Fibrillar structure of hemp fiber.

Fig. 5 Cellulose molecule.

The hemicellulose

Hemicellulose is a natural polymer like cellulose, consisting of carbohydrate monomers. However, hemicellulose consists of a variety of carbohydrate monomers, unlike homopolysaccharide cellulose. Thus, the monomers that hemicellulose consists of are arabinose, mannose, galactose, glucose, and xylose. Since hemicellulose has considerable side-branch groups, its structure is more open and non-crystalline. Hemicellulose is more hygroscopic than cellulose and attracts more water molecules due to its open structure. The degree of polymerization of hemicellulose in wood is about 100–200, which is very low when compared to that of cellulose, which is 10,000. The difference between wood and non-wood fibers does not appear in the content of cellulose, however, it does appear in the contents of hemicellulose and lignin. Non-wood fibers such as grasses (wheat, corn, rice) contain up to 40% of the major hemicellulose found in grasses, whereas wood fibers are composed of 25%–35% of hemicellulose by dry weight. **Fig. 7** illustrates a typical hemicellulose molecule found in a type of wood fiber named Arabinoglucuronoxylan (xylan) (Stokke *et al.*, 2013).

The lignin

Lignin is an extremely heterogeneous macromolecule that represents about 30% of the organic carbon in the biosphere. Lignin is totally amorphous, and unlike the other carbohydrate-based cellulose and hemicellulose, it contributes to the protection of the cell walls by working as the glue that holds the cells. Lignin has an aromatic structure represented by three precursors: p-coumaryl, sinapyl, and coniferyl alcohol (see **Fig. 8** (based on Stokke *et al.* (2013))). The contents of lignin in a vegetable fiber vary from 2% to up to 45% (Stokke *et al.*, 2013; Al-Oqla and Salit, 2017).

Mechanical Properties of Vegetable Fibers

Vegetable fibers (cotton, jute, hemp, flax, sisal, kenaf, coconut, abaca, wood,...) have biological structures mainly composed of cellulose, hemicelluloses and lignin. Cellulose is a polymer that, unlike the other components of the fiber that have an amorphous

Fig. 6 Organization of cellulose components in the cell wall of a typical plant fiber.

Fig. 7 Structure of hemicellulose (xylan) consisting of a xylopyranose backbone, with glucuronic acid (1→2) and arabinofuranose (1→3) side branches.

structure, has a largely crystalline structure that gives a modulus of elasticity of about 136 GPa compared to that of 75 GPa for glass fibers. Vegetable fiber is comparable to a composite material reinforced with fibrils of cellulose. The matrix is mainly composed of hemicellulose and lignin. The cellulose fibrils are helically oriented at an angle called the “microfibrillar angle”. This angle is located between the fibrils and the axis of the fiber. The degree value of the microfibrillar angle influences the stiffness of the fiber.

The properties of natural fibers are often subject to discussion due to the fact the techniques used to cultivate, extract or separate the fibers vary significantly, which may modify their behavior. For instance, the factors that can affect the properties of VF could be attributed to the variety, the conditions of cultivation (soil, treatment, climate), maturity, degree of preparation (retting, scutching, combing...), moisture content, crystalline structure (degree of crystallinity, degree of polymerization, cellulose type...), and morphology (cell diameter, microfibrillar angle, lumen size), etc. Usually, the amount of reinforcement and the orientation of fibers in a composite material set the elastic and rupture characteristics. Similarly, in a plant fiber, the physical properties of natural fibers are mainly determined by the chemical and physical composition, structure, the percentage of cellulose, the microfibrillar angle, the aspect ratio L/d (length/diameter: which is an important parameter allowing the transfer of charge between the fibers and matrix), the transversal section, and the degree of polymerization. To simplify, for a given percentage of cellulose, the

Fig. 8 Structure of lignin precursors.

Fig. 9 The average mechanical properties of different types of VF.

microfibrillar angle will be weak and the strength of the fiber will be higher; moreover, the microfibrillar angle will be significant and the elongation at breakage will be important. Strong dispersions of physical, mechanical or thermal property measurements make the characterization of VF more delicate. These dispersions follow the structural differences observed in the fibers. For example, the size of cells not only depends on the variety of the fiber to which they belong, but also on their maturation stage, their “meteorological history” and their location in the plant. The mechanical properties of different fibers from different origins of plants used for the reinforcement of common composite materials are shown in [Fig. 9](#) (based on [Chabert \(1988\)](#) and [Väisänen et al. \(2016\)](#)). By taking into account the natural behavior of these fibers, some dispersions can be noticed.

Fig. 10 Chemical analysis of some VFs.

Chemical Properties of Vegetable Fibers

The main constituents of VF are cellulose, hemicelluloses and lignin. Other products like proteins, pectin, starch, and inorganic salts are present in smaller amounts (Rowell, 1995). The chemical composition of VF depends on its origin, but in general, cellulose is always predominant with percentages by weight ranging from 22% for Sabai fibers to 85% for linters of cotton (see Fig. 10 (based on Sbiai (2011) and Väisänen *et al.* (2016))). Lignin concentrations vary from 7% to 24% by weight, and those of hemicelluloses from 12% to 27% by weight. These compounds are heteropolymers, which exhibit great variability in chemical composition according to their origin. The inorganic compounds, characterized by their ash content, also vary depending on the nature of the fiber. Thus, this content is about 1% by weight for wood lignocellulosic fibers and of the order of 14% for fibers from rice.

Physical Properties of Vegetable Fibers

Hygroscopic properties of vegetable fibers

The dimensional instability with respect to moisture is the main property of wood, which makes its use more delicate. When a tree is alive, it contains water that flows through its cells. The wood material, therefore, contains a certain rate of humidity, depending on the weather conditions. Water plays the role of plasticizer for the polymer chains constituting the cell walls, which is the reason behind the fact that the moisture content and diffusion phenomena govern all the characteristics of the wood. If not for constituent water, represented by the atoms of hydrogen and oxygen that compose the molecules of the polymer's structure, water is found in two forms:

- Free water: it fills the cells and the vessels, is held by capillary forces and is not involved in dimensional variations.
- Bound water: it is fixed on the polymers structure by physisorption or chemisorption. The forces involved are electrostatic or of the type of hydrogen bonds with hydroxyl groups.

The dimensional variation of hygroscopic material is mainly due to the water content, with the amount of water (bound water and free water) contained in the wood being characterized by a parameter called "moisture content of wood", which is defined as the ratio:

$$M(\%) = \frac{(W_h - W_0)}{W_0} \times 100 \quad (1)$$

where:

W_h : the humid weight of the specimen

W_0 : the anhydrous weight of the specimen

During the wood drying process, it is the free water that evaporates first. The fiber saturation point of the wood is reached when the moisture content is about $M = 30\%$. By continuing the drying process, it is the bound water which begins to evaporate. Dry wood in the air has a moisture content of 13%–17% according to the seasons. It can have a drier state when artificially dried; in particular, it reaches an anhydrous state after being dried for several hours in an oven at a temperature of 100–105°C. Therefore, it is conceivable that there is a moisture content threshold for which the adsorption sites are saturated (cell walls have the maximum amount of bond water). When there is no free water, the fiber saturation point (FSP) is reached. The moisture content at the FSP is very variable depending on the species, but is between 25% and 35% of moisture content for most types of fibers. Generally, it is more suitable to give a value of 30%, which corresponds to the behavior of the majority of species.

The moisture content of some types of VF is significantly different, as shown in Fig. 11 (based on the study of Ahmad *et al.* (2015) and Kocak and Mistik (2015)). This difference is related to the hydrogen bonding of cellulose and the amount of hemicellulose.

By submerging VF in water, the moisture content, in this case, will be beyond the FSP, including both the bond and the free water. In this context, as mentioned in the research study of Benmansour *et al.* (2014), the properties of moisture also depend on the aspect ratio of fibers. In this study, the authors evaluated the water absorption of date palm fibers as a function of immersion time. They found that the fibers with a small surface absorb more water compared to those with a larger surface (see Fig. 12).

Fig. 11 Moisture content of some selected VFs.

Fig. 12 Water absorption ratio of date palm fibers as a function of immersion time.

Fresh Properties of Cementitious Materials Modified With Vegetable Fibers

The incorporation of VF leads to a significant decrease in workability. This is due to the water absorbed by the VF. However, the mixture needs to have sufficient flowability for the casting process. A mixture that is too dry could lead to a final product that is insufficiently compacted, which would probably contain more voids. Conversely, a mixture that is too wet will lead to a decrease in mechanical strength.

The other important aspect of workability is the formation of fiber pellets, which is also known as the agglomeration of the fibers together during the mixing process. The degree of agglomeration depends on the type and length of fibers used, the volume fraction of fibers, and the size of aggregates in the cementitious composite (Bentur and Mindess, 2014). Fiber agglomeration should be avoided as it has a detrimental effect on mechanical strength. Some arrangements can be made during mixing to minimize the agglomeration effect. Normally, the progressive addition of fibers at the end of the mixing operation, when the other components are completely mixed, reduces this agglomeration effect. The use of a water-reducing plasticizer also makes it possible to substantially increase the workability without harming the mechanical performance of the composite (Sawsen *et al.*, 2015). Moreover, according to Aziz *et al.* (1981), the reduction of the granular dosage also makes it possible to limit the formation of pellets (Aziz *et al.*, 1981).

The flow ability of reinforced fresh mortar was negatively affected by the presence of fibers in the study of Çomak *et al.* (2018). This reduction (see Fig. 13) was attributed to the increase of water absorption by the increase of the fiber content. Nevertheless, the length of fibers has no effect on the flowability of cementitious materials (Çomak *et al.*, 2018).

Another aspect has a significant influence on the workability of fresh mortar, namely, the methodologies adopted to mix the VF homogeneously in the mortar matrix.

In this context, Chakraborty *et al.* (2013) tested three different processes of preparing the cement mortar composite by including 5 different fractions of jute fibers (0.5%, 1%, 2%, 3% and 4%). The first mixing process, which is termed as PS1, was conducted as follows: the slurry was made with 50% of the total quantity of cement and water, the fraction of chopped jute fibers was then added continuously during 10 min of mixing time, the remaining part of cement was mixed with the required quantity of sand separately for 5 min, the dry mix (sand and cement) was then added to the slurry (jute fibers, water, and cement) and mixed for 5 min, and finally, the remaining quantity of water (50%) was added into the slurry (Sand, cement and jute fibers). The second type of mixing, which is termed as PS2, was similar to PS1. The difference in this process was in the phase in which the fibers were incorporated. The jute fibers were first submerged in 50% of the total quantity of water, then 50% of the total quantity of cement was added and the slurry was mixed for 10 min. The remaining part of cement was dry mixed with sand and the dry mix was added to the slurry. Finally, the remaining part of water was added to the slurry. The third mixing process, which was termed as PS3, was performed as follows: the chopped jute fibers were immersed in water for 24 h until reaching full saturation, the saturated fibers were mixed with 50% of the total quantity of cement and water, and then the required amount of sand and remaining quantities of cement and water were added to the slurry.

The highlight of the results obtained (see Fig. 13 (based on Chakraborty *et al.* (2013) and Çomak *et al.* (2018))), showed that the workability decreased by using process PS1 and PS2 in the preparation of mortar due to the hydrophilic nature of the jute fiber. Nevertheless, the third type of mixing process, PS3, showed flowability values similar to that of the control mortar specimen. The reasons behind this difference can be explained by the fact that in preparation processes PS1 and PS2, the jute fibers were added

Fig. 13 Workability of cement mortar reinforced with: (i). Jute fibers (0%, 0.5%, 1%, 2%, 3% and 4%) using three different mixing process (PS1, PS2 and PS3), (ii). Hemp fibers (0%, 1%, 2% and 3%) with different lengths (Ref:0 mm, M6:6 mm, M12:12 mm and M18:18 mm).

dry into either the cement slurry (PS1) or into the water (PS2). In both cases, (PS1) and (PS2), the amount of water required for hydration of the cement was reduced by the presence of the jute fibers, which, as mentioned earlier, have a hydrophilic nature. Therefore, the significant reduction of workability by using preparation processes PS1 and PS2 is due to the incomplete hydration process of the cement mortar. In process PS3, however, the jute fibers were already saturated. The required amount of water for cement hydration was not affected by the presence of fibers since they are wet. Therefore, the workability of the mortar mixture prepared using process PS3 showed similar workability as that measured for the control mortar specimen.

The key factors that affect the reduction of the workability in cement mortars are the aspect ratio and the volume fraction of the fibers. The reduction of the workability could be remedied by the pre-treatment of fibers to reduce the chemical components that absorb the water. The VF could be pre-wetted before inclusion in the mixture. Otherwise, the absorption rate of fibers could be considered when preparing fiber reinforced mortar mixtures by adding a determined extra amount of water (Onuaguluchi and Banthia, 2016).

Mechanical Properties of Cementitious Materials Modified With Vegetable Fibers

The mechanical properties of VF reinforced cementitious materials, as with other fiber-reinforced concrete (FRC), are affected by a large number of factors (American Concrete Institute (ACI), 2009). The main ones are:

- Type of fibers: sisal, hemp, jute, coir, date palm, etc.
- Morphology of fibers: length, diameter, transversal section.
- Type of fiber's inclusion: single fibers, bundle, strand.
- Fiber surface: smooth, rough, coating agent.
- Matrix properties: type of cement, size of aggregates, admixtures.
- Proportions of the different constituents: W/C ratio, fiber content, proportion of aggregates.
- Mixing process: type of mixer, sequence of constituent's addition, method of fiber incorporation, period and speed of mixing. Implementation method: vibration standard, extrusion.
- Curing condition: air, water.

In this section, the mechanical behavior of cementitious composites reinforced with VF will be discussed based on the previous studies available in the literature. More precisely, the mechanical behavior will be analyzed in terms of compressive and flexural strength.

Compressive Strength

According to many researchers (Kriker *et al.*, 2005; Ozerkan *et al.*, 2013; Hamzaoui *et al.*, 2014; Lima *et al.*, 2014; Al-Rifaie and Al-Niami, 2016; Tian *et al.*, 2016; Tioua *et al.*, 2017; Belakroum *et al.*, 2018), the compressive strength of cementitious materials is negatively affected by the inclusion of VF. For instance, Kriker *et al.* (2005) mentioned in their study that the compressive strength decreased by increasing both the content of fibers and their length. The compressive strength of the concrete specimen reinforced with 2% by volume of date palm fibers in which the fiber length is 15 mm represents 90% of the compressive strength when compared to the unreinforced concrete specimen. However, the specimen reinforced with 3% of fibers of 60 mm length represents 55% of the compressive strength of plain concrete. The authors attributed this decrease to the increase in the number of defects and the non-uniformity of fiber distribution.

In a similar study, Tioua *et al.* (2017) investigated the compressive strength of a self-compacting concrete reinforced with two volume fractions of date palm fibers (0.1% and 0.2% by volume) of two different lengths (1 and 2 cm). In this study, two different curing conditions were utilized (laboratory and hot-dry climate). The authors concluded that specimens cured in a hot-dry climate had a higher strength when compared to those cured in the laboratory after 1 day of being cured. This was due to the accelerating effect of the temperature on the hydration rate. Moreover, the specimens cured in the laboratory had a larger compressive strength after 7 and 28 days of being cured. However, in both curing conditions, the specimens containing date palm fibers had a lower compressive strength compared to the control specimen. The authors attributed this decrease to the increase of the porosity introduced by the date palm fibers.

Other parameters, such as the saturation degree of the fibers, could influence the compressive strength of cementitious composites reinforced with VF, which was indicated by Hamzaoui *et al.* (2014) in a study on the mechanical behavior of modified mortar using dry and wet hemp fibers. In this study, the compressive strength decreased in both cases when using dry or wet hemp fibers. Moreover, the dry hemp fibers caused a significant decrease when compared to wet hemp fibers.

A new green composite material containing a high amount of fly ash (fixed to cement at a rate of 1.6) and reinforced with three different volumes of bagasse fibers (3%, 8%, and 12% by volume) was mechanically investigated by Tian *et al.* (2016). By increasing the content of bagasse fibers, a significant reduction of the compressive strength in early age could be noticed. For instance, at the age of 7 days, the composite reinforced with 3% of bagasse fibers showed a compressive strength value of 24.24 MPa. This value dropped by 51.7% and by 43.52% for composites reinforced with 8% and 12% of bagasse fibers, respectively. The authors indicated that this high reduction in early age is related to the unsaturated hydration of cementitious composites, which is influenced by the uneven

Table 2 Various compressive strength results of different cementitious materials blended with different VF reinforcements

distribution of water due to the hydrophilic nature of bagasse fibers. Nevertheless, the change in compressive strength of the composites at the age of 28 days became more stable.

Some studies mentioned that the addition of low quantities of VF could lead to beneficial results in compressive strength (Ozerkan *et al.*, 2013; Andiç-Çakir *et al.*, 2014; Çomak *et al.*, 2018).

Ozerkan *et al.*, (2013) noticed in a study related to the mechanical performance of cement mortar reinforced with date palm fibers that inclusion of 0.5% of date palm fibers has the desired effect on the compressive strength of cement mortar. This result was found due to the high compaction between the mortar matrix and the fibers, which led to a good homogeneity of this mix.

Andiç-Çakir *et al.* (2014) tested cement mortar composites prepared with the use of fine aggregates and coir fibers with an addition ratio of 0.4%, 0.6% and 0.75% by weight of the total mixtures. The authors indicated that the increase of coir fibers led to an increase in compressive strength, and this increase varied between 3.64% and 14.25% for the reinforced specimens with untreated coir fibers. Moreover, an increase varying between 9% and 17.94% was achieved for specimens containing alkali-treated coir fibers.

A similar result was obtained in the experimental study performed by Çomak *et al.* (2018), in which the authors mentioned that VF could have a good effect on the compressive strength of cementitious materials. In this study, cement-based mortar incorporating hemp fibers with a fiber content ratio of 1%, 2%, and 3% with different lengths of 6, 12 and 18 mm was investigated. The authors recorded an increase in the compressive strength of up to 30%. The authors considered that the long fibers' orientation to sample length was found to be better and contributed to a much bigger increase in compressive strength.

The results obtained from different studies concerning the effect of VF reinforcement on the compressive strength of cementitious materials are summarized in Table 2.

Flexural Strength

The studies carried out on the flexural behavior of the VF reinforced cementitious composites were highlighted. The plain matrix of cementitious composite presented a brittle linear behavior in flexural strength. The bio-composite samples, on the other hand, presented non-brittle behavior and continued to support a significant load after the maximum load. Sedan (2007) compared the mechanical properties of cement paste and cement matrix incorporating hemp fibers (16% by volume). For this purpose, three-point bending tests were carried out on these two materials after 28 days of being cured in water.

The author distinguishes that the bending behavior of the cementitious composite has three phases:

- Phase I: Quasi-linear behavior close to that of the cement paste specimen. In this phase, the efforts are mainly supported by the matrix.
- Phase II: Appearance of the first crack in the matrix just before reaching the peak load. Then, the forces are transformed to the fibers that support the load and in turn limit the propagation of the crack by their bridging effect.
- Phase III: Beyond the peak load (post-peak phase), the load decreases in a controlled manner, unlike the cement paste which breaks suddenly. The author associates this phase with a progressive rupture of the fiber/matrix interfaces, followed by the fibers pull-out.

The transition from a brittle matrix to a ductile composite material exhibiting controlled post-peak behavior is noted by all authors. However, this behavior transformation is not always accompanied by an improvement in flexural strength (Kriker *et al.*, 2005).

By analyzing the research studies carried out on the flexural behavior of cementitious materials reinforced with VF, it was noticed that the flexural behavior of these composites is related to the nature and the dimensions (aspect ratio) of fibers, the type of cementitious matrices, the dispersion of fibers in the matrix, and also to the preparation process that was adjusted to prepare the

VF (raw, wet, treated). Some of the results obtained by different researchers are shown in **Fig. 14** (based on Chakraborty *et al.* (2013), Coutts and Warden (1992) and Benaimeche *et al.* (2018)).

Chakraborty *et al.* (2013) studied the mechanical influence of jute fibers with 4 volume fractions (0.5%, 1%, 2%, 3% and 4%) by using three different processes (PS1, PS2 and PS3) of preparing the fibers, which was described in Section “Fresh Properties of Cementitious Materials Modified with Vegetable Fibers”.

The authors concluded that using processes PS1 and PS3 contributed to an increase of the flexural strength with a corresponding increase of the amounts of jute fiber up to 1%. However, using more than 1% leads to a gradual decrease in flexural strength (see **Fig. 14**).

Regarding process PS2, the flexural strength was gradually decreased with the increase of fiber inclusion. The authors attributed this decrease to the agglomeration phenomena of fibers when using this process in the preparation (PS2). Among all the processes used, the PS3 process exhibited the best fiber dispersion. Therefore, the mortar specimens prepared according to PS3 showed the highest value of flexural strength, in which it was improved by 16% for 1% of jute fiber reinforcement when compared to the control specimen.

In the recent study performed by Benaimeche *et al.* (2018), the mechanical behavior of cement mortar reinforced with date palm mesh fibers as a raw material was investigated. The authors indicated that a reinforced mortar specimen with 10% of DPMF leads to a decrease of about 50% in flexural strength. Therefore, it can be concluded that the addition of date palm fibers as a raw material does not have a beneficial effect on flexural strength.

In the research studies performed by Coutts and Warden (1992), flexural strength was found to be improved when using up to 8% of fibers (see **Fig. 14**). This may be explained by the specific processes of the fiber’s preparation, such as the Kraft and pulping process, as well as due to the casting process of the specimen by using a dewatering method to remove the extra amount of water.

Although the fiber’s dosage had a significant influence on the flexural performance of the cementitious composites, the length of the fibers was also a parameter of influence. Tung *et al.* (2012) studied cement mortars reinforced with flax fibers (see **Fig. 15**). The authors mentioned that the flexural performances of the composite are directly related to the length of the flax fibers. Initially,

Fig. 15 Influence of the fiber's length on the flexural strength of cement mortars reinforced with flax fibers.

the increase in fiber length resulted in an increase in flexural strength. However, from a length value of 30 mm, which is considered as a critical value, the strength no longer increases and instead begins to decrease. Nonetheless, it is still higher than that of the control cement mortar.

Conclusion

Based on the reviewed papers, the general conclusion can be summarized as follows:

- The mechanical behavior of VF showed a big margin between the lower and the upper values due to the variety in their chemical components.
- The cellulose molecule governs the total behavior of the fiber. This is due to the crystalline structure it has when compared with the amorphous structure of hemicellulose and lignin.
- The moisture content of VF in nature rises by up to 17% according to the weather. When submerging VF in water, the moisture content can reach a value of 400%.
- The addition of VF negatively affects the fresh and hardened properties of cementitious materials, in which the flowability of reinforced fresh mortar decreases with the corresponding increase of fibers. This can be attributed to the hydrophilic nature of VF. Nevertheless, it gives better results when adopting such a mixing process in which the fibers are added wet to the mixture.
- The compressive strength of cementitious materials decreases due to the low density of applied fibers.
- In terms of flexural strength, the use of VF as a raw material showed a decrease in flexural strength. However, as shown in the literature, such a chemical treatment adopted for the fibers, and such preparation methods of the composites, could bring a significant improvement.

This article showed the ability to use vegetable fibers in cementitious materials. These fibers can be used in construction practice for, among others, non-structural building elements.

Utilization of Waste Expanded Glass in Cement Composites

Damian Stefaniuk and Łukasz Sadowski, Wrocław University of Science and Technology, Wrocław, Poland

Introduction

One of the existing civilization problem is the problem of energy consumption. According to the statistics published by [European Commission \(2018\)](#) recently buildings in the European Union (EU) are responsible for approximately 40% of the energy consumption in that region. As a consequence, environmental and economic restrictions are still increasing. One of the efforts for construction industry is to obtain more energy efficient construction materials. It can be done by improving their thermal insulation properties. According to the [European Commission \(2018\)](#) the EU has set a target for all new buildings to be nearly zero-energy by 2020. Therefore, it is very likely that the production of heat-insulating materials with improved thermal insulation properties will continue to grow.

Another existing civilization problem is a generation of huge amount of different kind of wastes. The utilization of these wastes each year is getting to be more expensive. Thus, companies must compete not only for the best price, quality and widest variety, but also in the area of environmental protection. For example the construction industry is improving sustainability by increasing the use of recycled aggregates in production of cement composites. Usually 60%–75% of concrete volume can be occupied by an aggregate. Therefore, even partial substitution of the natural aggregate with recycled material can give obvious environmental benefits. It results in reduction of production costs and because of the re-use of waste materials there is no need to pay environmental taxes and put them into landfill.

The remedy for the existing civilization problems can be the application of lightweight aggregate made from different kind of wastes. Lightweight aggregate is characterized by good thermal properties and is made from recycled products. Lightweight aggregate can be used for the production of lightweight concrete. It has been used since early days of Roman Empire. For example the Colosseum and the Pantheon were partly constructed with lightweight aggregate from crushed brick together with crushed lava and pumice ([Kralj, 2009](#)). Recently, the most frequently used lightweight aggregate are based on expanded clay, shale, vermiculite, perlite, polystyrene, different kinds of pelleted or sintered waste, including waste glass, silica sludge, sewage sludge ash and residue from the polishing process of different types of stone (see, e.g., [Ducman et al., 2002](#); [Ducman and Mirtiĉ, 2009](#)). They can be sourced from inorganic artificial products (e.g., expanded/foam glass made of recycled glass) and inorganic natural products (e.g., expanded clay, shale, perlite, etc.).

Glass has been used for decades in various applications. As a result of it a large amount of glass waste is being generated. Glass has very good properties. It is non-flammable, has high compressive strength and it is not permeable for water (or even air). In addition, it is considered as long living material. Unfortunately, this last advantage of glass is simultaneously its drawback while it creates serious utilization problem.

The first attempts to use glass as an aggregate in concrete has been undertaken almost 60 years ago. However, no success was then achieved due to problems caused by the alkali-silica reaction (ASR). ASR is caused by reaction between the reactive silica in glass and highly alkaline solution of the cement paste. It results in excessive expansion and microstructure degradation of cement composite. In the last few decades many studies were conducted to investigate the influence of the particle size and type of the used glass on the ASR. It was shown, that ASR can be reduced, or even eliminated, when ground waste glass with particle size up to 100 μm is used. According to [Shayan \(2002\)](#), ASR can be also reduced by using a suitable pozzolanic material such as metakaolin, silica fume, fly ash or ground blast furnace slag. As a result, grounded waste glass can be successfully used as an additive in cement composites. Nevertheless, the use of grounded waste glass help to solve only the pollution and utilization problems since its addition to cement composites do not improve their thermal properties. Therefore, it is better to use the waste glass in concrete as lightweight aggregate.

Highly porous glass in the form of expanded (foam) glass can be used as lightweight aggregate. It can be also used in the form of blocks, gravel (foam glass gravel) and expanded glass granules ([Manevich and Subbotin, 2008](#)). As pointed out by [Manevich and Subbotin \(2008\)](#), expanded glass in different forms can be used for insulating industrial refrigerators, marine oil terminals, ships, as foundations in permafrost conditions or in atomic energy, where the fire safety requirements are highly rigorous. Since expanded glass itself has poor mechanical properties, it is widely used as a one of the constituent of cement composites to create both, heat-insulating and construction material, utilizing wastes at the same time. However, as each material, expanded glass granules have their practical limitations when using them as one of the constituent of cement composites. Therefore, this work presents the possibilities of the expanded glass granules use in cement-based mixes in order to look at the latest developments and point out the future perspectives.

A Look on the Materials and Methods

Preparation of Expanded Glass Granules

Expanded glass granules are produced by mixing fine ground waste glass with a proper expanding agent and firing the mixture at a high temperature above the softening point of glass. It is of the primary importance to use an agent that degasses at a temperature higher than the glass softening point but still within the range where the viscosity of the glass is high enough to trap the gas inside

Fig. 1 Most commonly used fractions of expanded glass granules as lightweight aggregate.

(see, e.g., [Ducman et al., 2002](#)). According to [Limbachiya et al. \(2012\)](#), the most common temperature used is in the range from 700 to 900°C. As pointed out by [Ducman and Mirtiĉ \(2009\)](#) foaming agents are usually chosen from carbonates, sulphides, water-glass, SiC, Fe₂O₃ and MnO₂. To achieve a granulated structure of expanded glass, usually the glass-expansive agent mixture is granulated in drum and plate granulators, fluid or fluidized bed reactors, without or with a binder (see, e.g., [Ducman et al., 2002](#)).

For the production of expanded glass granules usually waste glass crushed and grinded to a particles size less than 100 µm are used. For this purpose mainly flat glass, vertically dawn sheet glass, colorless bottle, half-white, green glass or rolled glass can be especially used. As pointed out by [Manevich and Subbotin \(2008\)](#) after additional processing also brown containers, lead crystals, electric-lamp and kinescope glass can be suitable.

Evaluation of the Properties of the Expanded Glass Granules

In most studies the properties of expanded glass granules, such as bulk/apparent density, porosity, water absorption and thermal conductivity, were reported. The porosity of expanded glass granules can be evaluated using mercury porosimetry, helium pycnometry and graphical analysis of the scanning electron microscope images. In addition, some other properties such as alkali-silica reactivity, compressive strength, crushing resistance, sound absorption coefficient and pore diameter were reported. Most properties were evaluated using standard procedures. In [Ducman et al. \(2002\)](#) alkali-silica reactivity was determined by the ASTM chemical test ([ASTM C 289, 1994](#)). Structure investigation like pore diameter evaluation was mainly conducted using scanning electron microscope or optical microscope.

The properties of expanded glass granules highly depend on the granule size. Therefore, it is important to measure each property separately for each granule size. Also the knowledge on the particle size distribution is crucial. Usually, the following granule sizes are used: 0.1–0.3, 0.25–0.5, 0.5–1.0, 1.0–2.0, 2.0–4.0 and 4.0–8.0 [mm] (see [Fig. 1](#)).

Amount of Substitution of Natural Aggregate With Expanded Glass Granules in Mortar and Concrete Mixes

Because of different sizes of expanded glass granules they can replace both, fine and coarse natural aggregate. Therefore, expanded glass granules, as the lightweight aggregate, are used in the production of mortar and concrete, depending on the size of granules. Full and partial substitution of natural aggregates by expanded glass granules were reported in various references. Applied ratio between the mass of the cement and the mass of expanded glass granules (c/EGG ratio), used size of the expanded glass granules (particles diameter, ϕ) as well as produced type of cement composite (mortar or concrete) reported in the literature are summarized in [Table 1](#). In addition, [Table 1](#) is supplemented with the value of the mass of expanded glass granules per 1 m³ of the cement composite to show the utilization amount of the waste glass in mortar/concrete.

Preparation and Curing of Mortar and Concrete With Expanded Glass Granules

The design, preparation and casting of cement-based mixes containing expanded glass granules are similar to the normal cement composites. However, higher water absorption of lightweight aggregate in comparison with natural aggregate can have a negative

influence on the workability of the fresh mix since it can absorb a certain amount of water from the mixture. To overcome this problem, two methods are widely used, i.e., pre-soaking the lightweight aggregate in water or using higher water to cement (w/c) ratio to compensate for the absorption of aggregate. In most cases of mortar and concrete with expanded glass granules production, the latter method is applied (see, e.g., Bumanis *et al.*, 2013) or no extra water is added when lightweight aggregate with low absorption is used (Yu *et al.*, 2013).

Because of the possible ASR reaction, low-alkali cement contacting low amount of Na₂O-equivalent is sometimes chosen when using waste glass as an additive. Nevertheless, in general, the use of different cement types can be found in various studies with no special reason or explanation. A comprehensive comparison of the cement type on the properties of lightweight concrete containing expanded glass granules was made in Bumanis *et al.* (2013) where eight different cement types were used.

Different additives are added into the mortar and concrete mixes, e.g., air-entraining agent, limestone powder, superplasticizer, nanosilica, etc. The cement type, w/c ratio and additives used in mortar and concrete mixes with expanded glass granules are shown in Table 2.

Mixing conditions are usually not given in details, but to prepare cement composites with expanded glass granules, standard procedures are usually used. For example, in Bumanis *et al.* (2013) all dry materials were mixed with hand mixer for 1.5 min, then 70% of water was added and all was mixed for another 1.5 min; finally, the rest of the water was added and mixing was continued for 2 min. In some cases also vibration was performed (see, e.g., Yu *et al.*, 2013).

Unfortunately, in most cases the proportions of the mixtures are not justified or designed with a proper care. Nevertheless, in few studies a particle packing model (the modified Andreasen and Andersen model) was applied in order to maximize the packing density of the granular solid materials (e.g., Yu *et al.*, 2013). It was shown, that optimized packing approach results in more compacted, homogeneous and characterized by lower porosity composite containing expanded glass granules.

Evaluation of Macroscopic Properties of Mortar and Concrete With Expanded Glass Granules

The properties evaluation of mortar and concrete with expanded glass granules are usually made by standard procedures adopted for conventional mortar and concrete specimens. The properties are usually evaluated for the fresh mixes and hardened samples after 28 days.

The following properties of fresh lightweight aggregate can be found in literature: air content, slump workability, consistence of fresh mortar by flow table method, density or compacting factor. In turn, the following properties are most commonly evaluated for hardened samples: density, water absorption, compressive strength, flexural strength, modulus of elasticity (static or dynamic) and thermal conductivity. As mentioned before, because of high content of SiO₂ in expanded glass it is possible that it may react expansively with alkalis in the cement. Therefore, alkali-silica reactivity have to be also measured. ASR is usually determined by testing mortar bars immersed in a 1 M sodium hydroxide solution for 14 days at the temperature of 80°C according to ASTM C1260-01 (2003).

Evaluation of Microscopic Properties of Mortar and Concrete With Expanded Glass Granules

Macroscopic properties depend on the properties of the cement paste, aggregates and the interfacial transition zone. Therefore, the properties of the interfacial transition zone should also be investigated in the case of cement composites. Physical as well as chemical characteristics of expanded glass granules can strongly affect the properties of the interfacial transition zone. Physical process is caused by the water absorption. In turn, as pointed out by Yu *et al.* (2013), chemical process can be caused either by pozzolanic reaction (between expanded glass granules and the alkaline solution) or an impregnation process (deposit of hydroxide in the pores of lightweight aggregate). The physical process occurs mostly in early age while chemical process occurs at later age.

Microstructure of mortar containing expanded glass granules (including interfacial transition zone) was usually investigated by the scanning electron microscope. However, some more sophisticated method was also used, i.e., X-ray micro-computed tomography (Lanzón *et al.*, 2012).

A Look on the Recent Results

Properties of Waste Expanded Glass Granules

The pores of expanded glass granules to some extent are interconnected, but most of them are separated and closed in the form of a honeycomb. It was shown in Yu *et al.* (2013) that expanded glass granules are not homogeneous because their pore sizes decrease closer to the outer surface and outer surface is mostly closed. Usually, the porosity of expanded glass granules can vary from 77% to 89%. However, in Limbachiya *et al.* (2012) expanded glass granules with much lower porosity (45%–48%) were used. The most commonly reported properties of expanded glass granules are presented in Table 3. The parameters were evaluated by authors themselves or the data was taken from the manufacturer. Note that, the measurement of very fine particles of expanded glass granules are subject to larger measurement error, e.g., water absorption evaluation (for more details see Liu *et al.*, 2010) in comparison with coarse expanded glass granules particles.

It can be seen in Table 3, that expanded glass granules are characterized by very low density (bulk density in the range 0.14–0.56 [g cm⁻³]), low thermal conductivity (0.069–0.071 [W m⁻¹ K⁻¹]) and high strength (crushing resistance up to 3.5 MPa). Despite the high discrepancies in water absorption results, in most cases the water absorption of expanded glass granules after 1 h is between 0.6% and 12%. In addition, expanded glass is a fire-resistant material with a very long lifetime in comparison with other heat-insulating materials. Temperature of use of expanded glass granules can reach 600°C.

Most properties of expanded glass granules depend on their density and granule size. In general, with increasing granule size of expanded glass granules their bulk density, thermal conductivity, compressive strength and water absorption decrease according to one of the manufacturer data (JSC Stikloporas, 2018, M. K. Čiurlionio g. 111, LT 66161 Druskininkai, Lithuania) (see Fig. 2).

Despite the many advantages of expanded glass granules, the alkali-silica reactivity tests of expanded glass granules according to ASTM C 289 (1994) showed that they are highly reactive and are the additional source of alkalis (Ducman *et al.*, 2002). Therefore, some precautions have to be taken when using expanded glass granules as lightweight aggregate in cement composites.

Properties of Fresh Mortar and Concrete Mixes With Expanded Glass Granules

Various mixes can be found in the literature characterized by fresh densities in the range 0.73 g cm⁻³ (Bumanis *et al.*, 2013) to 2.39 g cm⁻³ (Limbachiya *et al.*, 2012), slump workability from 30 mm (Limbachiya *et al.*, 2012) to 460 mm (Yu *et al.*, 2015) and flow table from 168 mm (Bumanis *et al.*, 2013) to 348 mm (Yu *et al.*, 2016). It was shown, that, in general, the use of lightweight aggregate made of waste glass has negligible effect on concrete workability (initial slump) but the compacting factor can decrease over time when lightweight aggregate content increases due to its higher water absorption capacity in comparison with standard aggregate (Limbachiya *et al.*, 2012).

Macroscopic Properties of Hardened Mortar and Concrete With Expanded Glass Granules

The properties of hardened cement composites with expanded glass granules reported in the literature are summarized in [Table 4](#). In specific, the properties such as dry density, water absorption, thermal conductivity, compressive/flexural strength at 28 days and ASR linear strain are presented.

As it can be seen, cement composites with expanded glass granules differ from regular concrete in a number of aspects such as improved thermal conductivity and lowered density. However, it is characterized by lower compressive and flexural strength as well as decreased modulus of elasticity.

The upper limit of the density of lightweight concrete is equal to 2 g cm⁻³ ([EN 13055-1, 2002](#)). Lightweight concrete is categorized to 3 grades: low density concrete (also referred as ultra-lightweight, super-lightweight or infra-lightweight concrete) with a dry density <0.8 g cm⁻³, moderate strength concrete with a dry density in the range 0.8–1.4 [g cm⁻³] and structural concrete with a density between 1.4 and 2.0 [g cm⁻³]. Therefore, it can be seen that in many cases expanded glass granules was used to produce ultra-lightweight concrete (see [Table 4](#)). Ultra-lightweight concrete is mainly used for insulation purposes because

of its low compressive strength. However, nowadays, when properly designed, ultra-lightweight concrete with moderate compressive strength (10.0–12.2 [MPa]) can be found in the literature (Yu *et al.*, 2015).

In general, three main approaches are used when utilizing expanded glass granules in cement composites. The first approach is to utilize waste glass while still remaining high properties of mortar/concrete. In this case high compressive strength was obtained (more than 20 MPa) while having much lower thermal conductivity (usually from 0.485 to 0.847 [$\text{W m}^{-1} \text{K}^{-1}$]) than ordinary concrete and lower density by about 25%–45%.

The second approach is to create the composite characterized with as low thermal conductivity as possible. In these cases the compressive strength is not the most important parameter. For example, ultra-lightweight concrete with expanded glass granules characterized by thermal conductivity equal to 0.12 $\text{W m}^{-1} \text{K}^{-1}$ and 28-day compressive strength of 10 MPa was obtained in Yu *et al.* (2015).

The last main approach is to produce the cement composite characterized with the highest ratio between mechanical and thermal properties. The modified Andreasen and Andersen packing density model seems to be very useful for this purpose. One of the best example is ultra-lightweight concrete reinforced by polypropylene fibers characterized by the compressive strength equal to 14.5 MPa and thermal conductivity equal to 0.165 $\text{W m}^{-1} \text{K}^{-1}$ (Yu *et al.*, 2016). Based on the literature data, Fig. 3 presents relationship between compressive strength and thermal conductivity of lightweight concrete containing expanded glass granules in comparison with other types of lightweight concrete.

According to Limbachiya *et al.* (2012) the lightweight aggregate made of waste glass do not affect the carbonation depth in comparison with standard aggregate. In addition, expanded glass granules can have positive effect when used as an additive in lightweight concrete production, e.g., faster increase of strength at early ages (Limbachiya *et al.*, 2012). In addition, lightweight concrete with expanded glass granules have lower open porosity and capillary water absorption in comparison with lightweight concrete with expanded perlite (Lanzón *et al.*, 2012) as well as higher resistance to water and chloride-ion penetration compared with lightweight concrete with expanded clay of even higher unit weights and regular concrete (Liu *et al.*, 2010).

Although the expanded glass granules are highly reactive, in many cases they do not cause significant expansion (ASR linear strain, see Table 4) and cracks in the mortar. Cement mortar tested in Ducman *et al.* (2002) achieved -0.047% of linear strain after 6 months of exposure (shrinkage instead of expansion). It was explained in Ducman *et al.* (2002) by the high porous structure of the glass aggregate that can accommodate the high amount of gel produced. The same conclusion can be found in Limbachiya *et al.* (2012) where authors showed that the silica gel formed can dissipate through the porous structure of expanded glass when using up to 50% of it instead of standard aggregate. On the contrary, in the paper (Bumanis *et al.*, 2013) it was shown that due to high expansion of lightweight concrete and strength loss, lightweight concrete with foam glass cannot be used in building industry even with low alkali (low Na_2O equivalent) cement (e.g., CEM I 52.5R) without additional operations to prevent deleterious reactions. However, a proper composition of concrete mix can lead to ultra-lightweight concrete with expanded glass granules without the risk of the alkali-silica reaction (see, e.g., Yu *et al.*, 2015). Laboratory results show that the use of air-entraining agent is an effective method to reduce or eliminate the ASR expansion since the expansive reaction products can permeate into additional pores.

Microscopic Properties of Hardened Mortar and Concrete With Expanded Glass Granules

The microstructure investigation using scanning electron microscope in Liu *et al.* (2010) shown improved interfacial transition zone between expanded glass granules and cement paste compared with conventional concrete containing natural aggregate. Micro-computed tomography investigation performed by Lanzón *et al.* (2012) confirmed good adhesion (no cracks or discontinuities in the interfacial transition zone) of expanded glass granules to the cement paste. Good quality of the interfacial transition zone can be caused by the fact, that expanded glass granules absorb a certain amount of water (higher than natural aggregate) and as a result in the surrounding cement paste there is reduced w/c ratio.

Fig. 3 Relationship between the compressive strength and the thermal conductivity of lightweight concrete containing expanded glass granules (in comparison with other types of lightweight concrete).

Nevertheless, in most studies the interfacial transition zone investigation was only qualitative in nature, based mostly on visual observation. Therefore, more quantitative analysis should be made, using scanning electron microscope, micro-computed tomography or nanoindentation, to better understand the physical and chemical processes that take place in interfacial transition zone in cement composites with expanded glass granules.

Conclusions and Perspectives

Waste glass in the form of expanded glass granules can be successfully considered as the lightweight aggregate in cement composites. Main three approaches seems to be the most suitable for waste glass utilization in cement composites:

- Utilize waste glass while still remaining high properties of cement composite (usually small amount of waste glass can be utilized),
- Produce the cement composite characterized with the highest ratio between mechanical and thermal properties (moderate amount of waste glass utilization),
- Create the cement composite characterized with as low thermal conductivity as possible (highest value of waste glass utilization).

Such composites differ from regular concrete in a number of aspects. Their main advantage is that they show a low thermal conductivity while still retaining good mechanical strength. In addition, crushed lightweight concrete with expanded glass granules may be used for further production of concrete what is proven in [Kralj \(2009\)](#). However, when producing this type of composite, the alkali-silica reaction should be always taken into account and a proper precautions should be considered.

Lightweight concrete with expanded glass granules can be used in high-rise buildings, long span bridges, buildings where soil conditions are poor, or specialized structures as offshore platforms, floating and marine structures (see, e.g., [Liu et al., 2010](#); [Yu et al., 2016](#)).

Based on the literature it can be seen that the following research should be undertaken for better understanding of the lightweight concrete with expanded glass granules:

- Parameters of hardened mixes should be investigated at early ages and after a longer times (usually the parameters of hardened mixes are evaluated only after 28 days of curing),
- More quantitative analysis of microstructure should be done to better understand the physical and chemical processes that take place in the interfacial transition zone,
- More research except [Huiskes et al. \(2016\)](#) using geopolymer as the binder instead of cement should be done in order to improve thermal properties of composite containing expanded glass granules. In addition it can create another possibility to overcome the problem of ASR,
- An attempt to correlate the micro- and macro-properties should be undertaken to more efficiently design the composition of composite with expanded glass granules.

Introduction

The cement production typically requires about 3.2–6.3 GJ of energy and 1.7 tons of raw materials (chiefly limestone) per ton (t) of clinker produced (Oss and Padovani, 2003). Moreover, it is followed by a significant emission of carbon dioxide (CO₂), and also nitrogen oxides, sulfur oxides and particulates. The average intensity of carbon dioxide emissions from total global cement production is 222 kg of C/t of cement (Worrell *et al.*, 2001). For these reasons, the worldwide cement production has known recently high interest toward the mineral addition in attempts to reduce the clinker manufacture activity.

In order to minimize the polluting and the expensive industrial process, the mineral additions could be found abundant in the nature. In particular, it could be found as the natural pozzolana from (a deposit of pumice ash or tuff, the explosive volcanic eruption, and opaline shales, rice husk ash and metakaolin) (Ciuperca, 2018). In addition, it could be manufactured as a fly ash which is a by-product that is obtained during the combustion of pulverized coal in the electric generation process. Moreover, another type of addition could be cited that is created during the quarrying operations of the aggregate materials and the ornamentals stone. Large quantities of fine by-products wastes generated such as quarry dust and marble sludge, which cause serious environmental problems. This fine by-product waste is basically a limestone material which is extensively used recently as cement replacement material or as fine aggregates (Galetakis and Soutana, 2016). The waste generated from the marble industry can represent as much as 80%–90% of the total extracted soil and stone (Sardinha *et al.*, 2016).

The present article reviews the recent contributions which deal with the valorization of marble powder in the cement-based materials. In particular, it focuses on the historical overview of the marble production and the marble wastes generated in some valorization domains as well as its physical, chemical and mineralogical composition. Finally, it summarizes the effect of the use of marble powder as cement substitution on the properties of fresh and hardened cement-based materials.

Historic Overview

The Romans discovered marble stone (Fig. 1). At first, they were used for religious architectural achievements like statues of deities, temples, tombs, and after a while, they developed its industry from the manufacture of floors, cladding, sculptures, statues, and others as a building material. Its manufacture passes through several operations, shaping, sawing and polishing, during these operations, waste including marble powder are produced. This powder can be stolen in the air by wind effect; this can pollute the environment considerably and can threaten even agriculture and public health. These problems have stimulated researchers for recycled it; at the same time, in the construction branch, there are many problems, the cost of cement materials, gas emissions during cement production, the aggressive environment, so the first idea that came to researchers, which is the incorporation of the marble powder in the production of the cement-based materials. Bartoli and Bartoli (1965) incorporated the powder into the mortar composition as a partial substitution of OPC with a proportion of 1% to improve its properties. The researchers do not stop here, Burnett (1977) tries to prepare a mortar based on this powder by increasing its incorporation percentage up to 25%, this mortar is used for the repair of tiles ceramic (fill the joints between the porous edges). Research continued until 1982 when it came Sadler (1982) who proposed a mixture of mortar contains 6.7%–20% of marble powder to make this mixture more economical without noticeable degradation of its physical characteristics. Until now, researchers still want to develop building materials and minimize its cost by recycling this waste. The marble powder generally used by researchers Egyptians, Turks and Indians because the rate of marble waste is higher in their countries.

Marble stone

Since antiquity, marble has been widely used as a material for sculpture and architecture. Marble is a metamorphic rock derived from recrystallized limestone or dolomite sedimentary, composed mainly of calcium carbonate (CaCO₃) and magnesium

Fig. 1 Historic overview.

Fig. 2 Marble manufacture and waste generating process.

carbonate (MgCO_3). It is generated by the influence of the pressure, the temperature and the action of vapors that come from the deep parts of the globe.

Marble characterized by various colors, which are usually due to various mineral impurities such as clay, silt, sand, iron oxides, or chert that are originally present as grains or layers in the limestone (Ghosh *et al.*, 2008) but the white is the most common.

Application of marble stone

Because of its strength, durability, formability, architectural adaptability and aesthetic satisfaction, the marble has utilized throughout historic time as an important building material. Marble industry comprises two major branches; the first produces the carved marble, it is blocks or slabs that meet size and shape specifications. The application areas of carved marble include building stone, monumental stone, ashlar, wainscoting, veneer paneling, tiling, statuary and others. The second produces the crushed and ground marble, which ranges in size from large blocks to fine granular.

Marble powder

Marble powder is an inert material of pure limestone produced during the extraction and treatment of marble stones (Fig. 2). Since antiquity, it was used as a coating material due to its perfect impermeability and served as pigments.

Application of marble powder

The manufacture of marble pass through several stages: extraction, sawing, shaping and polishing that generate waste including marble powder.

The marble powder can be used in many branches, are as follows:

- Coating, decorative plaster, paint.
- Ceramic industry.
- Glass industry (used as mineral powders).
- Manufacture of paper (stone paper).
- Manufacture of plastic materials.

Advantages of marble powder

The marble powder has many advantages it can be mentioned:

- An economic and environmental interest by recycling that allows to reduce the pollution.
- Marble powder can be used as a coating material.
- Marble powder can be used as an additive in concrete and mortar to improve its mechanical properties.
- Marble powder can be used in the manufacture of limestone-cement.
- Possibility of mixing with many materials.

Disadvantages of marble powder

During the manufacturing processes of the marble stone, only 20%–25% of the final product (waste) is obtained. In addition, the marble stone is not available in all places.

The application, advantage and disadvantage of marble stone and marble powder are briefly shown in Table 1.

Table 1 Application, advantage and disadvantage of marble stone and marble powder

	<i>Application</i>	<i>Advantage</i>	<i>Disadvantage</i>
Marble stone	● Building stone, monumental stone and ashlar ● Wainscoting ● Veneer paneling ● Tiling ● Statues	● Strength ● Durability ● Formability ● Architectural adaptability ● Aesthetic satisfaction	● Expensive ● Not available in all places
Marble powder	● Coating, decorative plaster and paint ● Ceramic industry ● Glass industry (used as mineral powders) ● Manufacture of paper (stone paper) ● Manufacture of plastic materials	● Reduce the pollution. ● Used as a coating material ● Used as an additive in concrete and mortar ● Used in the manufacture of limestone-cement. ● Possibility of mixing with many materials.	● The waste obtained is ¼ of marble ● Not available in all places.

Fig. 3 Chemical analysis of marble powder used in the existing literature research.

Marble waste rate in some countries

Several researchers have estimated the amount of waste after the operations mentioned previously.

- In Turkey and exactly in the Afyon region about 340,000 tons of marble waste resulting from 409 marble processing plants that produce 19% of the total slab in Turkey (Celik and Sabah, 2008).
- In Brazil, the amount of waste left after the process of mining and the manufacture of ornamental stone can reach up to 40% of the total volume extracted, while the amount of waste after cutting and sawing operations can easily reach 20%–25% of the total block volume (Saboya *et al.*, 2007).
- In India, from the marble industries about 6 million tons/year of waste is released through cutting, polishing, processing and grinding operations (Pappu *et al.*, 2007).
- In Egypt, the industrial area of marble and granite processing “Shaq Al-Thoaban” produces about 800.000 tons/year of waste (Hamza *et al.*, 2011).

Chemical and Mineralogical Compositions of Marble Powder

Several studies have carried out on marble powder to know its chemical and mineralogical compositions for incorporating in the mixture of concrete and mortar as partial replacement of cement or sand in order to obtain a cement-based material having good properties and intended for construction.

Chemical compositions

The X-ray Fluorescence (XRF) diffraction is generally used for the chemical analysis quantitative. The chemical compositions of the MP used in some different studies are presented in Fig. 3. By examining the results indicated in this figure it can be seen that the main chemical component of the marble powder is Calcium oxide (CaO). In addition, it also indicated the presence of small amounts of Silicon dioxide (SiO₂), Magnesium oxide (MgO), Iron and Aluminum oxide (Fe₂O₃ and Al₂O₃), with a loss on ignition around 40%. The results shown in the figure reflect the typical composition of a marble which is mainly composed of the calcite (CaCO₃) and the dolomite (CaMg (CO₃)₂). The chemical analysis results of marble powder are briefly shown in Fig. 3.

The ternary diagram CaO–SiO₂–Al₂O₃ showing position of marble powder and other cementitious materials is shown in Fig. 4.

As can be seen from this figure, the main components of cement are CaO and SiO₂ and it has a small amount of Al₂O₃.

By comparison to the cement, the fly ash has a higher placement in the diagram. In this case, it can be mentioned that its main components are SiO₂ and Al₂O₃. The main components of blast furnace slag are identical as cement but with higher amounts.

Fig. 4 Ternary diagram $\text{CaO-SiO}_2\text{-Al}_2\text{O}_3$ showing typical position of marble powder and other cementitious materials.

By comparison to the other cement-based materials, the MP is located at the bottom of the diagram and its main component is CaO . Furthermore, it has minor amounts of SiO_2 and traces of Al_2O_3 . Thus, its utilization as a partial replacement of cement leads to an increase of CH content and a decrease of C-S-H, this is attributed to the excess of CaO provided by MP (Toubal Seghir *et al.*, 2018).

Mineralogical compositions

X-ray diffraction analysis (XRD) is usually used for the determination of the mineralogical composition of mineral powder as shown in the Fig. 5 (Toubal Seghir *et al.*, 2018). The majority of the recent studies indicated that the most dominant crystalline mineral of marble powder is mainly calcite (calcium carbonate CaCO_3) (Chaid *et al.*, 2011; Ergün, 2011; Mashaly *et al.*, 2015; Vardhan *et al.*, 2015; Toubal Seghir *et al.*, 2018).

Utilization of Marble Powder in the Manufacturing of Cement-Based Materials

The choice of a suitable formulation of a cement-based material requires a compromise between three objectives: facility of implementation defined by its workability, strength referred to different stages of maturation and durability with respect to physicochemical attack from the environment.

Marble powder (MP) can be used as a partial substitution of OPC in the concrete and mortar, its effect is expressed by the following:

Effect of Using Marble Powder on the Properties of Fresh Cement-Based Materials

Normal consistency and setting times

According to research performed by Aliabdo *et al.* (2014), which is presented in Fig. 6. The amount of water needed by each mixture is not so much varied from each other by using MP with a specific area about $3996 \text{ cm}^2/\text{g}$ as cement substitution up to 15%. In addition, the initial and final setting times of OPC pastes are not also affected, as shown in Fig. 4. The results are almost similar to that obtained by (Toubal Seghir *et al.*, 2018) which used the MP with a specific area about $3869.46 \text{ cm}^2/\text{g}$.

The increase of the MP fineness up to $6700 \text{ cm}^2/\text{g}$ increases the water requirement of all samples containing MP. However, as visible from the results published in the literature, there is a sudden reduction in the initial and final setting times as shown in Fig. 7. Nevertheless, the setting times of all OPC pastes are complying with the limits of ASTM C 150 (Mashaly *et al.*, 2015).

The results of the effect of cement substitution on the consistency and setting times are briefly shown in Table 2.

Fig. 5 Typical XRD pattern of marble powder.

Fig. 6 Normal consistency and setting times.

Workability

The fluidity of the OPC pastes made by partially substituting cement with MP up to 50% at w/b ratios of 0.48, 0.50 and 0.52 was evaluated by marsh cone test; it is taken as the inverse of flow time. The literature results illustrated in Fig. 8 show that the maximum benefit of improved workability is achieved up to 10% of the added marble powder at w/b ratios of 0.50 and 0.52 where the flow time is almost identical (Vardhan *et al.*, 2015).

This ratio of substitution (10% MP) was used in the manufacturing of concrete by Ashish *et al.* (2016). The authors concluded that the use of MP with higher specific area leads to an increase of friction and a decrease of workability. Similarly, Rana *et al.* (2015) conducted a study on concrete mixes prepared with marble sludge (MS) at 0.38 w/c. On the other hand, Sardinha *et al.* (2016) indicated that the decrease of cement content using MS with lower specific area does not affect the workability.

The results of the effect of cement substitution on the workability are briefly shown in Table 3.

The density of the fresh cement-based material

In the research published in the literature it is visible, that the density of fresh concrete made with 0%, 5%, 10% and 20% of MP as cement substitution measured right after the mixes production slightly decreases as the substitution ratio increases (Fig. 9). This may be due to the fact that the MP has a lower bulk density than the cement (Sardinha *et al.*, 2016). On the contrary, Singh *et al.* (2017) concluded that the incorporation of WMS does not significantly affect the density of concrete.

Fig. 7 Normal consistency and setting times of OPC pastes.

Table 2 Effect of cement substitution on water requirement and setting times

Researchers	Marble type	Fineness (cm ² /g)	Optimum (%)	Consistency	Setting times
Aliabdo <i>et al.</i> (2014)	WMD	3996	10	Slightly reduction	Ignored reduction
Mashaly <i>et al.</i> (2015)	MS	6700	20	Increase	Sudden reduction
Toubal Seghir <i>et al.</i> (2018)	MP	3869.46	10	Ignored increase	Ignored reduction

Fig. 8 Workability of OPC pastes at various replacement levels of MP.

Effect of Using Marble Powder on the Hardened Properties of Cement-Based Materials

Physical properties

The physical behavior of cement-based materials represented in terms of density, water absorption, permeability, and porosity.

The density of the hardened cement-based material

Mashaly *et al.* (2015) determined the dry bulk density of water-cured concrete containing 10%, 20%, 30% and 40% of MS as cement substitution. They concluded that the incorporation of 10% and 20% of MS slightly increases the density by 0.5% and 1.4% respectively, due to the filler effect of fine MS particles that filling of voids among aggregate particles. While the substitution by 30% and 40% showed a reduction in bulk density by 2.3% and 2.8% respectively, due to the lower specific gravity of MS

Table 3 Effect of cement substitution on cement-based material's workability

Researchers	Marble type	Cement-based material	Optimum (%)	w/b	Workability
Vardhan <i>et al.</i> (2015)	MP	Cement paste	10	0.5–0.52	Improved
Rana <i>et al.</i> (2015)	MS	Concrete	10	0.38	Reduce
Ashish <i>et al.</i> (2016)	WMP	Concrete	–	0.42	Lower
Sardinha <i>et al.</i> (2016)	MS	Structural concrete	–	0.54–0.55	Ignored reduction

Fig. 9 The density of fresh concrete at various replacement ratio.

Table 4 Effect of cement substitution on fresh cement-based material's density

Researchers	Marble type	Cement-based material	Optimum (%)	Density
Mashaly <i>et al.</i> (2015)	MS	Concrete	20	Slightly increases
Toubal Seghir <i>et al.</i> (2018)	MP	Cement paste	–	Decrease almost imperceptible

when compared to the OPC. On the contrary, Toubal Seghir *et al.* (2018) observed that the incorporation of MP by 5, 10 and 15% as cement substitution in the manufacturing of air-cured cement paste slightly decreases the apparent density due to the presence of ultrafine particles provided by MP, and the specific gravity of the MP is lower than the specific gravity of the cement. However, the change in the apparent density was almost imperceptible.

The results of the effect of cement substitution on the density of fresh cement-based material are briefly shown in Table 4.

Water absorption

The incorporation of MP with the high surface area ($6700 \text{ cm}^2/\text{g}$) as cement substitution led to an increase of apparent porosity thus increases the water absorption, as presented typically in Fig. 10. However, the progression in curing time leads to decrease of these properties due to the filling of some pores by the hydrate product that represents twice of anhydrous OPC (Mashaly *et al.*, 2015). In fact, as mentioned in the literature, the tricalcium aluminate (C_3A) reacted with calcite (CaCO_3) which led to the forming of calcium carbo-aluminates (CCA) (Ergün, 2011; Arel, 2016; Toubal Seghir *et al.*, 2018). In addition, the CaCO_3 can be reacted with tetracalcium-aluminoferrite to form calcium carbo- aluminoferrites (CCAF) (Toubal Seghir *et al.*, 2018) that may increase the total volume of the hydration products and decrease the apparent porosity and water absorption of the hardened OPC paste (Mashaly *et al.*, 2015).

In the experimental study (Chaid *et al.*, 2011), it can be concluded that the increase of the surface area of MP decreases the capillary absorption coefficient, the authors incorporate the MP as cement substitution with fineness of about $12,000 \text{ cm}^2/\text{g}$, the typical results shown in Fig. 11 indicate that its incorporation in concrete samples can help to get concrete with low water absorption capacity. This is may be due to the filler effect of MP associated with porosity reduction (Mashaly *et al.*, 2015).

The results of the effect of cement substitution on the water absorption are briefly shown in Table 5.

Permeability

Rana *et al.* (2015) reported that the concrete containing 5%–15% MS showed better resistance to water permeation than the control mix. The impermeability of concrete was credited to lower capillary pores (pore size and pore distribution) and their

Fig. 10 Water absorption and apparent porosity of OPC pastes.

Fig. 11 Evolution of the capillary absorption coefficient versus time.

Table 5 Effect of cement substitution on cement-based material's water absorption

Researchers	Marble type	Fineness (cm ² /g)	Cement-based material	Optimum (%)	Water absorption
Mashaly <i>et al.</i> (2015)	MS	6700	Cement paste	20	Slightly increase
Toubal Seghir <i>et al.</i> (2018)	MP	12,000	concrete	–	Decrease

discontinuity. However, further addition of MS (more than 15%) could not compensate for the poor microstructure thus increased the permeability of concrete. Fig. 12 shows typical reduction in concrete permeability.

Porosity

Rana *et al.* (2015) measured the porosity of water-cured concrete made with MS by MIP (Mercury Intrusion Porosimetry) technique. They concluded that the porosity of concrete containing 5 and 10% of MS was found lower than that of the control concrete whereas the pores within the concrete mixture were identified as fewer and discontinuous. However, the increase of MS more than 10% led to an increase in the concrete porosity. Some other studies found that the substitution of cement more than 10% by MP reduces the porosity. As Aliabdo *et al.* (2014) which concluded that the substitution of cement by 15% of MD reduced the concrete porosity due to the filler effect of MD. Moreover, intersected substitution percentage was up to 20% of MS determined by (Mashaly *et al.*, 2015) which observed that cement paste and concrete mixes containing 20% of MS displayed lower porosity

Fig. 12 Concrete permeability versus MS content.

Table 6 Effect of cement substitution on cement-based material's porosity

Researchers	Marble type	Cement-based material	Curing condition	Optimum (%)	Porosity
Aliabdo <i>et al.</i> (2014)	MD	Concrete	Water	15	Reduce
Rana <i>et al.</i> (2015)	MS	Concrete	Water	10	Lower
Mashaly <i>et al.</i> (2015)	MS	Cement paste and concrete	Water	20	Lower
Toubal Seghir <i>et al.</i> (2018)	MP	Cement paste	Air	–	Increase

than the corresponding cement paste and concrete mixes prepared without MS at the different water-to-binder ratio. They explained the reduction of porosity by both physical and chemical effect of MS that fill some of the pores.

On the contrary, Toubal Seghir *et al.* (2018) observed that the incorporation of MP by 5, 10 and 15% in the manufacturing of air-cured cement paste led to an increase of the porosity which measured by methanol exchange method due to the decrease in the volume of hydrate products by the reduction of C_3S and C_2S in the cement paste, also due to an incomplete hydration process which resulted by water evaporation under lower relative humidity.

The results of the effect of cement substitution on the porosity are briefly shown in Table 6.

Mechanical properties

Compressive strength

The compressive strength (f_{cd}) of hardened cement-based materials is evaluated by testing of specimens prepared and cured according to a national or international standard.

Aruntaş *et al.* (2010) investigated the usability of waste marble dust (WMD) as cement substitution in cement production. Two types of cement were studied. In type I mixes, the mortar were prepared with Portland composite cement (PCC) which was substituted by WMD at levels 0%, 2.5%, 5%, 7.5%, and 10%. Type II mixes, the ordinary Portland cement (OPC) was used with same substitution ratio. The authors concluded that the f_{cd} of mortar containing WMD at a cement-substitution ratio of 10% was higher than those of mortar based on PCC by 10% and lower than those of mortar based on OPC by 14% at 28 days. However, Mashaly *et al.* (2015) concluded that the increasing percentage of marble sludge (MS) from 10% to 40% resulted in a decrease of f_{cd} by 17%, 9%, 21%, and 30%, respectively at 28 days.

Toubal Seghir *et al.* (2018) investigated the effect of using MP as a partial substitution of OPC (0, 5, 10 and 15 % by weight). The MP incorporated in the mixture was grinded in order to obtain its fineness in the OPC fineness range, they reported that the use of MP in air-cured cement paste decreases the compressive strength at all curing age (3, 7, 28 and 65 days).

Singh *et al.* (2017) investigated the hardened properties of mortar and concrete containing 10% WMS as a substitution of cement after 7, 28 and 56 days. They concluded that the f_{cd} was improved by using 10% of WMS in a mortar and less than 10% in concrete, this is attributed to micro filler effect of WMS. The use of WMS more than 10% lead to decrease the f_{cd} . In a similar investigation, Boukhelkhal *et al.* (2016) evaluated the f_{cd} of SCC prepared with partial substitution of cement by MP. A continuous decrease in compressive strength was observed with increasing substitution ratios, the reduction in compressive strength was attributed to the use of an inert mineral unlike to the pozzolanic admixture. Contrarily, Aliabdo *et al.* (2014) concluded that the substitution of cement by WMD (10%) improved the f_{cd} of concrete at 0.40 w/c. However, the increase of w/c up to 0.5 lead to decrease the f_{cd} . Similar lines, (Ashish *et al.*, 2016) reported a decrease of f_{cd} with the incorporation of 10% MD in concrete at 0.42 w/c.

Table 7 Effect of cement substitution on cement-base material's compressive strength

Researchers	Marble type	Cement-based material	Optimum (%)	Compressive strength (f_{cd})
Aruntaş <i>et al.</i> (2010)	WMD	Mortar	10	Satisfactory
Corinaldesi <i>et al.</i> (2010)	MP	Mortar	–	Reduced
Ergün (2011)	WMP	Concrete	5	Improved
Gesoğlu <i>et al.</i> (2012)	MP	SCC	–	Systematic reduction
Aliabdo <i>et al.</i> (2014)	WMD	Cement paste and concrete	10	Improved
Mashaly <i>et al.</i> (2015)	MS	Cement paste and concrete	20	Appropriate
Ashish <i>et al.</i> (2016)	WMP	Concrete	–	Reduced
Boukhelkhal <i>et al.</i> (2016)	MP	SCC	–	Reduced
Singh <i>et al.</i> (2017)	WMS	Concrete	10	Improved
Toubal Seghir <i>et al.</i> (2018)	MP	Cement paste	5	Acceptable

Ergün (2011) examined the mechanical properties of concrete using WMP as cement substitution, the superplasticizer was used to decrease water demand in the production of concrete and to keep it constant in all mixes. The substitution of 5% cement by WMP affect positively the f_{cd} . The increase in f_{cd} was attributed to the filler properties of WMP and low water demand caused by using a superplasticizer admixture.

According to Arel (2016), in Turkey the concrete production costs US\$40/m³ and the use of MD substitution of 5% increases the f_{cd} by 12% thus reduced the cost by US\$4/m³, while the use of 10% MD reduced the cost by US\$7/m³ correspondingly, decreases the global annual carbon dioxide (CO₂) releases also by 12%. Worldwide, both cement production and the CO₂ emissions will decrease by 10%.

Generally, the use of 5%–10% MP as cement substitution was beneficial and more than 10% decreases the f_{cd} , this decrease was attributed to the significant reduction of C₃S and C₂S in the cement-based material, which is mainly responsible for the development of compressive strength. It is commonly known as the dilution of pozzolanic reactions (Ergün, 2011; Aliabdo *et al.*, 2014; Mashaly *et al.*, 2015; Toubal Seghir *et al.*, 2018).

The results of the effect of cement substitution on the compressive strength are briefly shown in Table 7.

Chemical properties of hardened cement-based materials

Carbonation

Rana *et al.* (2015) measured the carbonation resistance of concrete prepared with MS in the accelerated carbonation chamber of $5 \pm 0.2\%$ carbon dioxide concentration at 50–65%RH and $27 \pm 2^\circ\text{C}$ temperature. Concrete prepared with MS showed poor resistance to carbonation than the control concrete. At all substitution ratios, the carbonation depths gradually increased. This increase due to the lower bicarbonate alkalinity of MS (89 mg/l) compared to that of Portland cement (113 mg/l).

Chloride ion migration

Rana *et al.* (2015) reported that the chloride diffusion coefficient of the concrete containing 5%–10% MS as cement substitution was found lower in comparison to the control mix. The fine particles of MS help to fill the capillary pores this phenomenon explains the lower apparent chloride diffusion coefficient obtained.

Corrosion resistance

Rana *et al.* (2015) measured the corrosion activity of concrete containing MS using the half-cell potential with CSE (Copper-Copper sulfate electrode). The use of 5%–10% MS as cement substitution enhances the corrosive resistance of concrete. This indicates that the fine particles of MS occupy voids and densify the concrete microstructure. However, the incorporation of 15%–25% MS deteriorated the corrosive resistance of the concrete mix.

Chemical effect of marble powder on the hardened cement-based materials

Prassianakis and Prassianakis (2004) defined that the marble is a metamorphic product of pure limestone, resulting from its transformation under the heat and/or pressure effect. During its extraction and treatment operation, the WMP produced. Several studies pointed out that this waste is an inert by-product. However, as mentioned by Ergün (2011), Arel (2016) and Toubal Seghir *et al.* (2018) the calcium carbonate (CaCO₃) provided by WMP can be reacted with tricalcium aluminate C₃S presented in cement which formed calcium carbo-aluminates (CCA). Toubal Seghir *et al.* (2018) pointed out that the CaCO₃ also reacts with Tetra-calcium-aluminoferriite to form calcium carbo-aluminoferriites (CCAF).

Toubal Seghir *et al.* (2018) analysis the specimen of cement paste containing MP using SEM-EDX. They mentioned that the use of MP as cement substitution, lead to an increase of calcium hydroxide (CH) and a decrease of silicate hydrate thus decreases the C–S–H content, this decrease allowed for a decrease of compressive strength and an increase of porosity.

Vardhan *et al.* (2015) were studied the mortar specimen by XRD diffraction technique for identification of phases present in the hardened mortar containing marble stone dust (MSD). The results indicate that MP is an inert material and there is no change in the phase composition qualitatively of the cement-based materials.

Conclusions

The present article reviews the recent peer-reviewed paper available online on the utilization of marble powder in the cement-based materials as cement substitution. The main conclusion could be summarized in the following points:

- (1) The consistency and setting times of cement pastes are not affected when using the MP as a cement substitution with almost similar fineness to that of cement. Whereas, the increase in fineness of MP showed an increase of the water requirement and a sudden reduction in the setting times.
- (2) The marble powder influence positively on the workability of the fresh cement-based material by an inclusion ratio up to 10%.
- (3) The fresh concrete density showed contradictory results in the literature. Some researchers have mentioned that the density of fresh concrete decreases with an increasing percentage of MP. Others have pointed out that the density affected slightly by using MP as cement substitution.
- (4) The incorporation of MP as cement substitution led to an increase of apparent porosity thus increases the water absorption of cement paste, contrary, the use of MP in the production of concrete decreases the capillary absorption coefficient thus reduced the porosity.
- (5) The dry bulk density of cement-based materials slightly increases by using up to 20% MS due to its fine particles that filling voids among aggregate particles. Some other authors found that the use of MP up to 15% slightly decreases the apparent density due to the lower specific gravity of MP compared to that of cement.
- (6) The porosity of water-cured cement-based materials showed a decrease by using MP as cement substitution due to the effect of MP that filling some pores.
- (7) The porosity of air-cured cement-based materials showed an increase by using MP as cement substitution due to the reduction of C_3S and C_2S . In addition, due to an incomplete hydration process which resulted by the water evaporation.
- (8) The incorporation of MP up to 10% as cement substitution give acceptable results in term of compressive strength.
- (9) The use of 10% MP decreases the cement production and the global annual CO_2 emissions by 10%. Thus, reduced the cost by US\$7/m³.
- (10) The marble powder is an inert material; however, the $CaCO_3$ of MP can be reacted with C_3A of cement and Tetracalcium-aluminoferrite.
- (11) The SEM-EDX of cement-based materials indicates that the addition of MP resulted in an increase of CH and a decrease of silicate hydrate thus decreases the C–S–H content, this decrease allowed for a decrease of compressive strength and an increase of porosity.
- (12) XRD diffraction technique appears that marble powder does not lead to much change in the phase composition of the mixture.

The general conclusion of this review is that the incorporation of marble powder as cement substitution was beneficial. The properties of cement-based materials with more than 10%MP will be inappropriate. While replacing cement with 5%–10% marble powder yielded the favorable results. The substitution at appropriate ratios, marble powder has no adverse effects on cement-based materials quality.

The existing research showed the possibility to utilize the marble waste in cement-based materials. The future research in the field of the utilization of marble waste may be related to the applications in structural concrete. These applications may also include non-structural parts of the buildings such as for example the concrete floor screeds.

Bio-Based Materials in Sportswear Applications

Jane E Wood, Manchester Metropolitan University, Manchester, England, United Kingdom

Main Principles of Biomimetics

Through millions of years of evolution, biological structures have relied on their ability to adapt to their changing environments to survive (Ngo, 2015). The overarching principle of biomimicry is that of taking inspiration from these biological structures and mechanisms and transferring the concepts to the man-made world. Whilst some of the biological key properties can be considered as self-assembly, reproduction, self-repair, and redistribution of vital resources, man-made structures are usually designed with one aim, which remains unchanged during the useful life of the product (Kapsali and Dunamore, 2008).

To adapt biological principles to a man-made world, design principles must be adopted to ensure an effective solution is found. “Bottom up” and “top down” are two such methods that are used.

The premise of the bottom up approach is that of the discovery of a process or structure existing in the natural world. The phenomenon is studied to gain an understanding of its biological principles. Once fully explored, potential uses of these findings are identified in the man-made world. Conversely, the top down approach originates with the identification of a gap in the market for which a biological principle is researched as a solution.

Whilst these approaches are useful, they are considered basic methodologies and do not allow for creative approaches to problem solving. The lack of creative approach is considered by some researchers as the main reason why biomimetics has not been adopted more rapidly into mainstream use.

Natures Inspiration for Sportswear

In the field of performance sportswear, functionality is a key driver of the product's success. Major players in the field, such as Nike and Adidas, are constantly in pursuit of the latest innovation that will elevate their products in both the professional performance and mass market.

Biomimetics is a relatively new field of research and as such, many developments and practical implementations are still in their infancy, but, used effectively, could give a competitive advantage to a manufacturer. As previously discussed, the natural world has been used for inspiration for several years, yet the science itself is still unfolding. Phenomena such as spider silk, crab shells, and bird beaks provide new insights into impact protection, whilst sharkskin, bird feathers, and humidity sensitive bacteria have allowed great design leaps in performance sportswear. The following sections aim to discuss some of these phenomena in more detail, alongside specific applications.

Biomimetics in Sports Apparel

Biomimetic textiles can be thought of as “a platform to transfer properties and functionalities identified in biological systems into fibrous structures” (Kapsali, 2015, p. 77). One of the first examples of this was the development and subsequent patenting of Velcro®. This technology is universally recognized and has numerous applications, yet it all began with the investigation of the sticking of burdock plant burrs to animal fur in 1941. The discovery that each burr is covered in needle-like hooks led to the development of a textile that has applications well beyond the scope of apparel.

Whilst the natural environment offers a rich supply of inspiration from which to develop cutting edge textiles, the field has been slow to develop and translation into useable garments still remains a largely untapped resource. Leading academics in the field, such as Veronika Kapsali, suggest this is due to the disconnect between design and technology disciplines in the field of textiles and apparel design (Kapsali, 2016).

However, there have been some developments in sportswear that may prove to pave the way for a wider uptake in biomimicry in apparel.

Swimming/Water Sports

In the field of competitive swimming, there has been much attention focused on drag and the streamlining of the swimmer's body to reduce this.

Many underwater animals are covered in scales and secrete a mucus that contribute to a reduction in drag friction and protect against abrasion. Sharkskin was first studied in relation to the reduction of drag in aircraft shells (Vincent, 2009). However, sharkskin differs in that the “scales” are more akin to ribbed skin (dermal denticles), and channel the water over the body, reducing pools of slower water currents and thus improving the aqua dynamics of the creature (Kapsali, 2016).

In 2000, Speedo (a swimwear company and part of the Pentland group) launched Fastskin™. This full body swimsuit is made from fabric that is designed to mimic sharkskin. However, this was not the only special design feature. This development also focused on the shape of the swimmer's body in the water and how the flow of water around it impacted movement and speed. Thus, the suit was designed to be extremely tight fitting, effectively changing the wearer's body shape and improving aqua dynamic flow. It was suggested that this was the feature giving the most impact on performance and further suits were developed with the focus shifted to the change in body shape and how to achieve this. Ultimately, this was so successful that it was deemed to give an unfair competitive advantage to those athletes who could afford the suit, leading to a ban by FINA in 2010.

However, the concept of sharkskin was not completely abandoned. Today it is used in the coatings of boat and ship bodies to reduce algae build up, water friction, and ultimately improve fuel consumption (Garty, 2015).

Keeping warm in the water has long been a puzzle for sportswear developers. Many animals live in the water and it is commonly understood that animal survival in colder water temperatures is reliant on a thick layer of subcutaneous blubber. However, not all animals possess this thick fat layer. Researchers at the Sheico group in Taiwan (a sporting goods manufacturer) wanted to find ways in which surfers could keep warm in the water, without an increase in wetsuit weight. Current neoprene wetsuits rely on the trapping of air within the foam like structure for insulation – however, improved insulation is only achieved by increasing the thickness of the neoprene and therefore the weight of the suit.

This led to the study of semiaquatic mammals (such as beavers), who keep warm when diving by trapping air within their fur. Working with a research team from Massachusetts Institute of Technology (MIT), a series of models were created with rubber “hairs” on the surface of varying lengths and densities. By submerging these in liquids at various speeds, these prototypes could be evaluated in terms of surface drag, hair movement, and subsequent air bubble entrapment. From this work, a mathematical model was developed that can be used to quantify the air entrapment of a given textile material with a hair like surface, enabling further development in this field to take place (Coxworth, 2016).

In contrast to this, a penguin ensures insulation in arctic waters via a different mechanism. Muscles at the base of the animal's feathers, alongside the feather construction, are capable of creating an adaptable coat to allow the animal to survive a variety of environmental conditions. This allows a waterproof barrier to be created for diving, which can then adapt to an insulating, windproof barrier once out of the water.

This ability to essentially change the configuration of the feathers is considered a “variable geometry” principle, which has been used in clothing to impart similar insulating effects. Using two layers of fabric at right angles to each other “skews” the fabric. It is the degree of skewing between the fabrics that determines the amount of air trapped between them. The wearer can inflate or deflate the garment as required, thus adapting the product to the environmental conditions. W.L. Gore in collaboration with Nike used this principle in their Airvantage range, suggesting the products were a “personally adjustable insulation system” (Drier, 2002).

Extreme Climate Protection/Athletics

One of the problems faced by sportswear designers is that of moisture management. This plays an important role in wearer comfort and keeping the body dry and cool (or warm where necessary) is a constant challenge.

The ability of the clothing to allow perspiration to flow away from the body and evaporate is key in sportswear clothing design – breathability is critical to the comfort of the wearer. There have been many adaptations in garment engineering to accommodate this, such as zipped vents in the torso of hill walking jackets and meshed areas incorporated into gym wear. However, biomimicry is allowing the textiles themselves to be engineered to address this issue.

Fabric manufacturers such as Schoeller® textiles and MMT textiles have used nature as inspiration for moisture control – namely the pinecone. The pinecone is highly sensitive to temperature and humidity, with its scales opening in dry, warm weather to allow the seeds to escape and spread, and closing in wetter, cooler conditions to protect the seeds. Schoeller® has adapted this principle to a fabric structure, marketed as c_change™ technology, whilst MMT textiles have created the Inotek® fiber – both solutions imparting moisture management properties to the textile (MMT, 2018; Schoeller, 2018).

Another approach to moisture management has taken inspiration from plant respiration (Stegmaier et al., 2008). The pores on leaves, known as stomata, open and close to allow gaseous exchange with the environment. This process of transpiration allows moisture to be lost from the leaf. Stomatex® is a neoprene-based textile, with small dome shaped indentations on the surface (Fig. 1), each with a small pore at its center (Stomatex, 2018). Perspiration and heat from the body accumulate in these chambers and are allowed to escape as the pores open during flexing of the textile with the body's movement. Equally, cooler, drier air is allowed in from the outside, maintaining a comfortable microclimate within the clothing (Kapsali, 2016). Stomatex® is used in a variety of sporting applications, including heat acclimatization suites for the England rugby Union squad and British Olympic team (Stomatex, 2018).

Whilst not strictly considered biomimicry, microbiology has been used by researchers at MIT to address the issues of moisture control in sports garments. Rather than taking the principles of the bacterial mechanisms and copying these in a man-made setting, it is the bacteria themselves that have been used to impart the required properties. The bioLogic project is a collaboration between MIT, The Royal College of Art, and New Balance. A bio printer is used to deposit a hybrid film containing specific bacteria (*Bacillus subtilis natto*) onto fabric. This bacterium is known for its sensitivity to humidity and therefore the printed fabric is able to “sense” when the body is becoming warmer through increased perspiration production. The bacteria can expand or contract depending on the moisture levels and this action is used in garment design. Ventilation zones are created in the garment in the form of fabric

Fig. 1 Stomatex[®] neoprene fabric showing domes with tiny pores at apex on (a) fabric face, (b) fabric reverse.

flaps. These zones are engineered at points on the body to be most effective at perspiration evaporation. As the body heats up, the bacteria react to the increased moisture and the flaps open to allow perspiration to evaporate; as the body cools and perspiration levels drop, the bacteria react again and the flaps in the fabric close. This is using the bacterial world at its best to create a truly responsive garment.

Biomimetics in Sports Equipment

Rackets

Dunlop Sports has been an innovator in the field of tennis rackets for many years. In 2011 they launched a range of rackets, named the Biomimetic range, based on three principles inspired by nature – Sharkskin, gecko feet, and a beehive.

The main body of the frame's structure is carbon based, which has long been established in racket manufacture. However, HM6 carbon has a honeycomb molecular arrangement. It is well documented that the honeycomb in a beehive, whilst made of wax, has improved strength due to the hexagonal formation of the structure. Arranging carbon atoms in this way not only improves the structural strength of the racket, vibrations through the frame after the ball is struck are also reduced.

The outer skin of the racket frame is covered in dimples, marketed as Aeroskin. It is suggested that this mimics the skin of a shark, using the same principles of enhanced hydrodynamics to improve the movement of the racket through the air. This effect is also believed to reduce air friction and therefore less energy is expended with each strike of the tennis ball.

Finally, the grip of the racket has been inspired by feet of the gecko. The ability of the gecko to scale walls has been studied at length, revealing this ability to be down to microscopic hairs that protrude from the pads of the animal's toes. It is the combined action of the hundreds of thousands of each of these hairs and the force they impart that exerts the huge gripping force observed by researchers. This principle is applied to the grip of the racket, marketed as "Gecko-Tac." Dunlop claims that "Gecko-Tac technology provides up to 50%* more grip and tack than previous Dunlop technology, giving greater control, feel and precision" (Dunlop, 2018).

Protective Helmets

Nature provides us with many opportunities to study the field of impact protection. It comes as no surprise that the natural world has evolved a variety of solutions to this problem. Several of these principles have been investigated as a means to protect the human body from impact.

An obvious place to start with biomimicry for impact control is to look at creatures with hard exoskeletons. Crustaceans have been studied for many years, but a recent development is the research by MIT looking at the structure of the scaly-foot snail. This snail's shell has the ability to withstand prolonged, high pressure from crab claws and the MIT team have found the shell comprises three layers: Two more rigid layers with a thicker, more flexible, "padding" layer sandwiched between these. The innermost layer sitting beside the body is made of aragonite (calcium carbonate), common in many mollusks. The outermost is pyrite and greigite (iron sulfides) – this snail is the only animal in which these minerals are found. The presence of iron sulfides acts as a shock absorber, dissipating energy from impact by creating thousands of microcracks in the shell, preventing one large crack and ultimately the complete rupture of the exoskeleton. This composite material is of great interest as it is so novel in the animal kingdom and researchers are looking at how these properties can be transferred and developed for applications such as body armor, bicycle, and motorcycle helmets (Kapsali, 2016).

Hedgehogs are able to protect themselves from falls or blows to the body by rolling into tight balls, causing their spines to protrude. The spines take the full force of the impact, bending under the force, but rarely breaking. This dissipates and absorbs the kinetic energy of the collision, preventing serious damage to the soft torso underneath. This principle has led researchers to investigate how this concept can be incorporated into protective helmets, particularly in the field of American football (Hedegemon, 2018). Whilst this could be an interesting development, current work shows that spines do break on occasion. Whilst these are regrown in nature, they would not be replaced in a man-made structure, reducing the efficacy of the helmet protection over time if this issue is not sufficiently addressed.

Animal paw pads have also been identified as "natural" shock absorbers. Studies of the members of the feline family show that when falling from height, the animals have the propensity to fall on their feet. However, for the heavier animals, such as lions, the stress on the legs is far greater than, for example, the domestic cat. The lion's paw pads have evolved over time to absorb impact energy, which serves not only to protect the skeletal structure, but to "silence" the animal's movements, critical whilst hunting in the wild (Hubbard *et al.*, 2009; Ninomiya *et al.*, 2011). Studies conducted on other animals such as foxes, dogs, and beavers have all revealed shock absorbing properties. It is thought that there is a honeycomb type structure of collagen fibers found in paw pads that contributes to the shock absorbing properties. It is this principle that has been harnessed in the development of horse riding helmets.

Impacts to the head, whilst causing crushing trauma to the skull, can also cause torsion damage to the neck leading to severe injury. This has led to further developments in protective headwear – and further investigation into how nature can lead the way.

Rams take repeated blows to the head as part of the battle against other males in the flock. Constant hitting of this magnitude would cause severe damage to the human skull. Whilst a ram's skull is extra strong, any damage to the neck by the kinetic forces of the repeated blows is minimized by a thin lining of fluid around the ram's skull. This goes some way to dissipating the energy of the striking force, therefore reducing the chance of neck damage. Some high-end motorcycle helmets use this principle. The helmets are made of a tough outer layer covering a viscous gel (allowing some movement), which in turn covers the inner shock absorbing material. If the rider hits their head at high speed on the ground, the skull is protected from the shock and impact whilst the neck is protected from violent whipping injury.

Other motorcycle helmet designs take their inspiration from bird beaks. The inner part of a toucan's beak is almost honeycomb like in texture, made from a scaffold of keratin and calcium, whilst the outer part is covered with keratin in a scale formation. This makes for a lightweight, but extremely tough shock absorbing structure. Researchers at the University of California believe that whilst this structure is useful for protective helmets, there could also be an application in car body design (Rovner, 2005).

Other birds have also been used for inspiration in garments for impact protection. Many studies have been conducted around the woodpecker beak and the bird's ability to withstand the repeated impacts of drumming on trees with no damage to its brain. It has been found that the bird's porous bone structure dissipates low frequency vibrations, whilst the outer case of the beak is extremely strong to resist fracture. Coupled with a unique support structure for the tongue, a woodpecker can drum at speeds of 22 beats per second with decelerations of 1200 g, with no damage to soft or nervous tissue. At decelerations of 80–100 g, humans are often left concussed. Using these principles, researchers have designed shock absorbers using glass beads, rubber, and aluminum to mimic the bird's skull and beak structure. However, these concepts could easily be transferred to either protective helmets or protective wear in sports such as Formula One racing in which drivers are often subjected to dramatic decelerations during the course of a circuit (Yoon and Park, 2011; Marks, 2011).

Shoes

Silk has always been of interest to the textile industry due to its high strength, heat and moisture management properties, and lustrous appearance. Spider silk is of particularly high strength and it is the molecular arrangement of the proteins within the spider silk structure that imparts these properties (Holland and Vollrath, 2008). It is therefore imperative that this structure is mimicked as closely as possible if one is to replicate these high-performance properties through artificial spinning techniques. Through several years of product development, a German company, AM Silk, claims to have developed a fiber that mimics spider

silk in terms of strength, elasticity, moisture management, odor management, and feel against the skin. The fiber, named Biosteel[®] is also claimed to be 100% biodegradable (Biosteel, 2018).

Adidas have long been trailblazers in innovative technologies and it comes as no surprise that as a company they are keen to explore the benefits of biomimicry. In collaboration with the AM Silk team, they have developed a product based on the Biosteel[®] fiber and incorporated this into a high-performance shoe, unveiled at the Biofabricate conference in New York in 2016 (Biofabricate, 2018). The shoe, part of the Adidas Futurecraft range, is an additional development in the Adidas quest for sustainable product innovation. James Carnes, Vice President of Strategy Creation at Adidas, states: "In a year of ground-breaking innovations from Adidas, the announcement of our partnership with AMSilk – and the unveiling of the Adidas Futurecraft Biofabric shoe – is another step in our commitment to redefining the sports industry. This concept represents premium innovation. By using Biosteel[®] fiber in our products, we have achieved an unrivaled level of sustainability. We are moving beyond closed loop and into an infinite loop – or even no loop at all. This is a pioneering stride forward beyond sustainability into a new territory of bionic innovation" (Adidas, 2018).

Summary

Biomimicry has a potential for a huge impact in sportswear and sporting goods development. However, uptake has been slow within the sports industry and many developments have not progressed beyond the concept stage.

Nevertheless, using creative design principles, it is possible to envisage a time when much of the product development in this field takes its inspiration from nature in one form or another. It can be considered that the botanical world is much more efficient at evolving to meet the ever-changing demands of its environment and as developers relatively new to the field, we would be foolish to not take nature's lead. For example, the natural shock absorbing ability of bird beaks and animal paw pads has the potential to lead to innovative solutions for protective equipment for humans, and bacteria may hold the key to moisture management control in sports apparel.

In the future, using nature as inspiration, it may be possible to solve some of those issues that human engineers still have not solved, even after hundreds of years of study.

Biodegradable Packaging Materials

Ishrat Majid, Lovely Professional University Phagwara, Jalandhar, Punjab, India

Mamta Thakur and Vikas Nanda, Sant Longowal Institute of Engineering and Technology (Deemed To Be University), Longowal, Punjab, India

Introduction

Packaging is a necessity in today's world as nearly all the consumer goods in the market usually appear with some kind of packaging materials that not only provide protection from external abuses but also fulfill customers' desires, as well as industry requirements for product information, convenience, and safety. Traditionally, several kinds of materials, such as glass, metal, wood, plastic, paper, or combination of materials, are widely employed for varying categories of packaging like primary, secondary, or tertiary packaging. The primary packaging materials that are in contact with the consumer goods are often brought home by the customers and are diffused at the household level, and get contaminated or damaged when coming in contact with other materials. On the other hand, secondary packaging materials are employed to pack the many units of primary packaged items, while tertiary packaging materials facilitate the transportation of manufactured goods in wooden pellets, cardboard boxes, or plastic wrap. Thus these secondary and tertiary packaging materials are seen by retailers, wholesalers, and manufacturers and are thus comparatively simpler to gather and categorize for reuse or recycling. However, the primary packaging materials often cause reuse or recycling issues because they cannot be easily sorted (Davis and Song, 2006). This leads to the complication of waste disposal contributing to the concern on environment pollution.

Recently, great efforts are being taken to develop such packaging materials that not only improve performance but are also easy to recycle and reuse. A new class of packaging materials following these properties is the biodegradable packaging materials derived from the renewable biological sources known as biopolymers, which offer excellent protection to the product and are easier to degrade after use, exhibiting the potential as an eco-friendly alternative to traditional petroleum derived materials like metal, glass, paper, plastic, etc., which are not biodegradable (Khan *et al.*, 2016). The biodegradable packaging materials are highly beneficial in one time use or short-duration packaging requirements like disposable cups and plate, garbage bags, diapers, medical devices, food and beverage package, etc.

Biodegradables mean anything that must be degenerated and compostable under the suitable conditions of temperature, moisture, and oxygen leaving behind no toxic or harmful residues. Thus the biodegradable packaging materials are those that undergo the process of degradation by naturally occurring organisms, such as bacteria, yeast, or fungi (Sorrentino *et al.*, 2007), and can be used as humus or fertilizer when composted (Siracusa *et al.*, 2008). Currently, various kinds of biodegradable and compostable polymers, such as starch, cellulose, chitosan, and lignin, are commercially available. Even some synthetic polymers are mixed with minute amounts of biopolymers for making them biodegradable.

The best biodegradable materials are derived from the renewable and bio-based sources called biopolymers. The main function of biodegradables like any other packaging material is to protect the contents from surrounding and maintain its quality throughout the storage life. Therefore, other characteristics like mechanical (tensile strength, tear and burst strength, etc.) and barrier properties, such as permeability of vapors, gases, light, etc., are equally important. The biopolymers are effective barriers against vapors and gases. But their mechanical and barrier properties can be improved by blending two or more biopolymers. Several active components or additives like antimicrobials, color, nutrients, antioxidants, etc. can be incorporated for increasing their performance (Clarival and Halleux, 2005). Thus, the biopolymers serve as an eco-friendly alternative for the use of nonrenewable and nonbiodegradable plastic based packaging materials. The study of recyclable and biodegradable polymers is an interesting and growing area in packaging science but immense research is required for improving their performance, thermal, mechanical, and physical characteristics, and commercial use, which might be possible in a few years.

The few developments of biodegradable polymers are mentioned as follows:

1. LDPE-starch blend were commercialized under the trade name Ecostar® in 1993 (Siracusa *et al.*, 2008).
2. Alexandre and Dubois (2000) manufactured the biopolymer-layered silicate nanocomposites that have remarkably enhanced the physical characteristics including higher gas barrier attributes, tensile strength, and thermal stability.
3. Li *et al.* (2003) revealed that the lignin would accelerate the thermal degradation of poly(L-lactic acid) (PLLA) when the content of lignin was more than 20%.
4. Al-ltry *et al.* (2012) improved the thermal stability, mechanical and rheological characteristics of polylactides (polylactic acid – PLA), polybutylene adipate-co-terephthalate and their blends using the reactive extrusion with functionalized epoxy in July 2012.
5. Khankrua *et al.* (2013) employed the silica nanoparticles to increase the onset and inflection temperature of thermal degradation in PLA, polybutylene succinate (PBS) as well as poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) nanocomposites. However, the mechanical properties were slightly improved at low concentration of silica and worsen at the higher levels of silica due to the agglomeration of silica in the polymer matrix.
6. Nevalainen (2013) developed a heat-sealable biodegradable packaging material, a package or a container produced thereof, and used the resin in the extrusion coating.

Fig. 1 Classification of biodegradable packaging materials based on the major constituents present and the origin of ingredients and their synthesis. PBS, polybutylene succinate; PCL, polylactic acid; PHA, polyhydroxyalkanoate; PHB, polyhydroxy butyrate; PLA, polylactic acid; PVA, polyvinyl alcohol. Reproduced from Clause, J.W., 2000. Bio-based packaging material for food Industry. European Concerted Action Project, pp. 13–50. ISBN: 87-90504-07-0.

Types of Biodegradable Packaging Materials

The biodegradable packaging materials can be classified into several categories as shown in [Fig. 1](#) based on different criteria. Broadly, on the basis of major constituent present, they can be of two types:

1. Biodegradable polymers: these possess certain degree of intrinsic biodegradability. These are basically synthetic oil derived polymers. For example, polyhydroxy butyrate (PHB), polycaprolactone (PCL), and polyvinyl alcohol (PVA).
2. Biopolymers: as the name suggests, these are biologically derived polymers or long chain biomolecules like starch, cellulose, proteins, etc., which are naturally decomposed into eco-friendly metabolic products.

However, the most common criterion considered for classification of biodegradables is the source or origin of raw materials and their synthesis. According to this, biodegradable materials are classified into three types:

1. Natural polymers or polymers derived from biomass.
 2. Synthetic polymers or polymers chemically synthesized from renewable sources.
 3. Microbial polymers or polymers derived from microorganisms.
1. Natural polymers: the commonly available natural polymers are derived from animal, marine, and agricultural sources, which include the polysaccharides, such as starch, cellulose, chitosan, gums etc., proteins like animal extracted protein (casein, collagen, gelatin, etc.), and plant derived proteins (zein, gluten, soy, etc.) and lipids including cross linked triglycerides ([Garcia et al., 2000](#); [Bertan et al., 2005](#); [Karnnet et al., 2005](#); [Perez-Gago and Krochta, 2001](#)). Most of these polymers are hydrophilic and crystalline in nature, which might cause several issues in moist food packaging, but these polymers are effective barrier against gas transmission.

Among these polymers, starch is the most widely used as packaging material, and is mainly derived from corn, potato, or rice. The starch alone cannot produce films having sufficient mechanical strength, and therefore are often blended with other materials or chemically or genetically modified because starch when exposed to moisture may swell and undergo deformation. The major

Fig. 2 Cellophane film for packaging of confectionery products and tea. Reproduced from Molenveld, K., van den Oever, M., Bos, H., 2015. Biobased packaging catalogue. Wageningen: Wageningen UR Food & Biobased Research.

disadvantage of starch-based polymers is their brittleness, which can be minimized by the incorporation of biodegradable plasticizers, such as glycerol, urea, polyhydroxy compounds, etc., by reducing the water activity. Several starch-based polymers include PHB, polylactide, and polyhydroxyalkanoate (PHA).

Cellulose, the most abundant natural polymer, is commonly used as paper or cardboard due to the presence of hydroxyl groups and regular structure leading to the formation of crystalline microfibrils and fibers containing strong hydrogen bonds. Cellulose in its raw form is very difficult to use as it is hydrophilic and crystalline in nature possessing poor mechanical properties. Therefore, it must be treated with chemicals like NaOH, H_2SO_4 , CS_2 , etc. to produce cellophane having excellent mechanical characteristics. Cellophane (Fig. 2) has been extensively used in commercial food packaging for products with long shelf-life. Likewise, several cellulose derivatives, such as carboxy-methyl cellulose, methyl cellulose, ethyl cellulose, cellulose acetate, hydroxyethyl cellulose, etc., are widely used.

Chitosan or chitin, the second abundant polysaccharides after cellulose is employed for the production of films or specifically edible coatings with high gas barrier properties and sometimes used with another films lacking gas barrier features. Moreover, the chitosan and chitin absorbs the heavy metals' ions, and they also possess antimicrobial properties, which reduces the oxidation process and is beneficial for increasing the shelf life and quality of food products particularly (Gemili *et al.*, 2009).

Proteins, made up of amino acids, are highly desirable to modify the required characteristics of packaging materials due to the presence of unique side chain in their structure. There are typically two kinds of proteins employed for synthesis of packaging materials: (1) protein derived from animal sources (casein, collagen, whey, etc.) (2) protein derived from plants (gluten, zein, soy, etc.). Protein based packaging materials have excellent gas barrier properties but they (except keratin) are adversely affected by their hydrophilic nature like starch-based polymers. Therefore, they also need to be blended with other polymers or must be chemically or microbiologically modified.

Casein, the milk-based protein, when processed with suitable plasticizers, turns from brittle and stiff to flexible materials perfect for film blowing. Irrespective of its comparatively high cost, it is still widely employed for bottle labeling due to its outstanding adhesive properties. Gluten based polymers are highly glossy, provide ambient moisture resistance, and do not dissolve in water. But they may absorb some water on immersion. Gluten carries immense scope as biopolymer packaging material due to its low price and abundance. Soy protein possesses similar performance characteristics like gluten due to the presence of disulfide linkages in both cases. The cheapest protein, keratin, is extremely difficult to process due to the high amount of cysteine. The material derived from keratin is water insoluble and completely biodegradable in nature. Collagen, the structural protein in animal tissues, is highly insoluble and difficult to process due to its fibrous nature. On the other hand, whey proteins, byproducts from the cheese industry, are widely employed as edible films and coatings.

Several lipid components like fatty acids, natural waxes, resins, and vegetable oils are generally incorporated in the films to provide hydrophobicity so that moisture barrier properties can be improved.

2. Synthetic polymers: this category usually includes PLA, PCL, PVA, polyglycolic acid (PGA), PBS, etc. Among these, PLA, the polymer of lactic acid, was the first biopolymer employed over industrial scale because lactic acid is simply produced from the carbohydrate based feedstock, such as agricultural crops (wheat, rice, maize, etc.) and waste or byproducts derived from the agriculture and food industry. The PLA properties may alter significantly from the semicrystalline to amorphous materials based on the proportion of D-PLA/L-PLA. The high content of L-PLA leads to the lower degradation of polymer because of higher crystallinity (Kale *et al.*, 2006). Therefore, the right ratio must be selected to produce PLA films that can be easily processed and have improved performance characteristics. The PLA based films possess higher molecular weight, good gas and moisture transmission properties and water solubility resistance, and are compostable as well as recyclable. They are used to pack food products (Fig. 3) with low shelf-life. PLA is commercialized in industry under different names by several companies, such as Natureworks PLA developed by the Natureworks LLC, United States (Siracusa *et al.*, 2008).

PCL is a thermoplastic as well as completely biodegradable polymer obtained from the nonrenewable sources, such as crude oil. It is a linear semicrystalline polymer that is soluble in several kinds of solvents. It is typically not employed to pack food products but when blended with starch, it produces a fairly biodegradable material that is mainly used for trash bags. This polymer

Fig. 3 Disposable cup and trays made from polylactic acid (PLA). Reproduced from Molenveld, K., van den Oever, M., Bos, H., 2015. Biobased packaging catalogue. Wageningen: Wageningen UR Food & Biobased Research.

offers good chemical resistance to oil, water, chlorine, and solvent with very low viscosity and melting time too. Due to its low glass transition temperature (around -60°C), it is employed as compatibilizer, while formulating the polyurethane. Commercially, PCL is observed under different trade names, such as Tone[®] from Union Carbide (Texas), CAPA[®] from Solvay (Belgium), Celgreen from Daicel (Japan), etc. (Pawar and Purwar, 2013).

PVA is derived from the partial or complete hydrolysis of polyvinyl acetate, offers good water solubility, and is fully biodegradable under aerobic or anaerobic conditions. It is employed for several applications in the nutraceutical, medical, and food industries. PVA is also considered a useful polymer matrix to entrap enzymes.

Glycolic acid on polymerization leads to the synthesis of PGA that is linear aliphatic, semicrystalline (46%–52% crystallinity), and fully biodegradable polyester. It offers excellent mechanical properties. It is generally insoluble in majority of nonpolar solvents (except hexafluoroisopropanol) due to its crystallinity. It shows the glass transition temperature of $35\text{--}40^{\circ}\text{C}$ and possesses high melting point, nearly $220\text{--}225^{\circ}\text{C}$ (Nair and Laurencin, 2007).

PBS and its other copolymers are derived from the condensation reactions of glycols like ethylene glycol and 1,4-butanediol with the aliphatic dicarboxylic acids like succinic and adipic acid. Bionolle is the first commercial biodegradable polyester resin developed by Showa High Polymer (Japan). In addition to PBS, several polymers have been synthesized from these condensation reactions, such as polyethylene succinate (PES) and PBS-co-adipate (PBSA). PBSA, a copolymer, is obtained when adipic acid is added. PBS, a white crystalline thermoplastic, has moderate melting point varying from 90 to 120°C and very low glass transition temperature (-45 to -10°C), which falls in between the glass transition temperature of polyethylene (PE) and polypropylene (PP) thus resulting in the similarity of PBS mechanical properties with PE and PP. PBS shows a better processability than that of PGA and PLA. On the incorporation of adipates, the tensile strength of polyester reduces in PBSA while other physical attributes remain unaffected. PBS has the highest tensile strength among the polyesters but the copolymers PBSA (60/40) and PBSA (80/20) exhibit modified elongation features.

3. Microbial polymers: this class includes the polymers that are synthesized from the microbial fermentation of polysaccharides. It is a quite recent and innovative field that has immense potential in industry. This category typically includes the polymers, such as polyhydroxy alkanates (PHA), PHB, PHBV, etc., and microbial polysaccharides like pullulan and curdlan. The polyalkanoates have a more hydrophobic nature than the polysaccharide derived materials leading to the production of a material with good moisture barrier properties but poor gas barriers. The PHA family is widely employed, and is synthesized from the sugars or lipids using bacterial fermentation. The polymer is usually synthesized from the fermentation process in microbial cells and is extracted using solvents like methylene chloride, chloroform, or propylene chloride. Being thermoplastic in nature, it has a wide range of melting points varying from 40 to 180°C based upon the monomer employed in production. PHB is the most common type of PHA among more than 100 PHA composites and is synthesized from the 3-hydroxybutyrate monomer. It carries similar properties like PP but is more brittle and stiffer, while PHBV is less tough and stiff. It degrades under both aerobic and anaerobic conditions forming CO_2 and H_2O in the former case and methane in the latter.

Several kinds of waste from the food and agriculture industry may be used as C-source to synthesize a range of PHA polymers. The PHA/PHB based films exhibit better performance than the conventional films like PE, PP, etc. and may be used to replace those. However, the major drawback in their commercial use is the high cost of manufacturing route. The film properties may be altered by changing the proportions of hydroxybutyrate (HB) and hydroxyvalerate (HV) by controlling the growth media. The high amount of PHB provides a stiff and strong film, while polyhydroxyvalerate (PHV) modifies the toughness and flexibility.

The utilization of microbial polysaccharides, such as xanthan, pullulan, curdlan, etc., as a packaging film is a novel concept and needs biotechnological techniques. Pullulan is synthesized using *Aureobasidium pullulans* from substrates containing sugars and is fairly water soluble, linear, and exopolysaccharide. It is employed for packing in several industries like food, medicine, and cosmetics. It is tasteless, odorless, nontoxic, and biodegradable in nature. Pullulan based films are generally transparent, homogeneous, heat sealable, printable, flexible, edible, and are a good barrier to oxygen but have poor mechanical properties (Freitas et al., 2014). These are employed to inhibit the fungal growth thus making them suitable for food applications particularly. Curdlan, the bacterial polysaccharide, is produced from *Agrobacterium biovar* and *Agrobacterium tumefaciens* and is a linear

Table 1 Commercially available biopolymers and their manufactures

β -(1,3)-glucan consisting of glucose units. It is mainly used as a gelling agent in the food industry but has enormous potential in the development of packaging films, which is yet to be discovered.

On the other hand, xanthan is produced by the aerobic fermentation of *Xanthomonas campestris* using sucrose or glucose as its major carbon source. It is a heteropolymer consisting of repeated glucose, mannose, and glucuronic acid in 2:2:1 ratio and also pyruvate and acetyl substituent groups. It is highly viscous, water soluble and nontoxic in nature. Not much data is available about the potential of xanthan in the packaging sector. This may be due to the high cost of production. However, acerola when wrapped with xanthan coating exhibited reduced weight loss, respiration thus maintaining the color and enhancing the shelf life (Quoc *et al.*, 2015).

Currently, several kinds of biopolymers are used commercially, as described in Table 1, that are synthesized from the starch (Fig. 4(a) and (b)), cellulose (Fig. 4(c) and (d)), PLA, PCL, or other kind of biodegradable packaging materials. However, extensive research is required in future to modify the properties of biodegradable packaging materials and to reduce their cost of production too.

Properties of Biodegradable Packaging Materials

The knowledge about properties of packaging materials is essential as they predict the shelf life of product and package. Generally, the small molecules of vapors, gases, water, and other liquids can be moved in and out of the package wall thus adversely affecting the product quality and shelf life. Sometimes the light penetrates the packaging materials and speeds up the oxidation reactions thus reducing the shelf life. Therefore, the properties of any biopolymer are described in detail as:

1. Gas and oxygen barrier properties: specific environment is needed to maintain the quality and freshness of many food products during storage. For that purpose, a certain gas mixture mainly consisting of carbon dioxide (CO₂), oxygen, and nitrogen or their combinations is incorporated in packages to ensure the optimum quality and safety. Therefore, the packaging materials must possess the definite gas barriers to sustain the established gas concentration in the package (Clause, 2000). Scientists have compared the gas barrier properties of biodegradable polymers with the traditional mineral oil derived packaging materials as shown in Fig. 5. It can be observed that biopolymers exhibit quite good resistance to the oxygen transmission and currently, many efforts are being carried out to modify the barrier properties of biopolymers. However, the oxygen transmission rate (OTR) is higher in bio-based packages than the traditionally used polymers, which may increase the oxidation reactions and reduce the shelf-life of product (Auras *et al.*, 2003). Likewise, the CO₂ barrier property of polymers is also important mainly in the case of fresh produce packing.

Traditional high barrier films include the combination of many layers to produce a film with the required attributes. The most commonly used laminate is made up of ethylene vinyl alcohol (EVOH) or polyamide-6 (PA6) layer along with low density polyethylene film (LDPE) film, which fuses the gas barrier features of EVOH or PA6 with the excellent sealing, mechanical strength, and moderate water vapor barrier properties of LDPE. Likewise, two or more bio-based polymers can be combined together to develop the polymer film carrying the necessary attributes. As seen in Fig. 2, the starch-based polymer along with plasticized chitosan may become a cheaper alternative to the currently used materials, such as EVOH or PA6.

2. Water vapor barrier properties: the water barrier properties of packaging material depend on the kind of product to be packaged. For powder, the equilibrium moisture content of products is important to maintain its shelf-life and the moisture

must be restricted inside the package. The water vapor must be transmitted inside of packaging materials for fresh produce to avoid dehydration, while bakery products need packages that should inhibit the permeability of water vapor.

The major limitation of bio-based packaging materials is their hydrophilic behavior because many products (some discussed above) require moisture-free conditions. When water vapor barrier properties of biopolymers are compared with the mineral oil-based materials as shown in Fig. 6, a composite biopolymer can be developed whose transmittance rates are somewhat near to the traditional plastics. The biodegradable packaging materials are a good choice in case of products that require high water vapor

transmission. Intense research has been carried out to improve the water barrier properties of bio-based materials either by combining several layers or using nanotechnological or biotechnological techniques.

3. Light barrier properties: the radiation energy derived from sunlight either in the form of visible or UV light speeds up the deterioration reactions that adversely affect photosensitive products. Light also acts as a catalyst to increase the rancidity of lipid based foods. Further, light can also induce the oxidative degradation in the polymers resulting in the weakening and discoloration of the polymers including both traditional and bio-based packaging materials. In order to avoid the photodegradation of polymers and products, UV stabilizers/absorbers can be incorporated in the packaging materials (Borghetti and Coltro, 2007).
4. Thermal and mechanical properties: in addition to barrier properties, the thermal and mechanical properties of biopolymers are equally important not only for processing but also in the case of product modeling (like sheet extrusion, injection molding, blow molding, thermoforming, film forming, etc.) derived from these materials. Commercially, several containers are employed to pack or store the product below room temperature; therefore, the mechanical properties under such conditions must be known. The thermal properties of bio-based polymers are nearly similar to the traditional polymers. For mechanical properties, a wide range of tests, such as tensile strength (MPa), percent elongation at break and yield (%), and elastic modulus (GPa) must be carried out and obtained values can be compared with the commercial conventional polymers. Standard tests should be performed to determine the impact and compressive resistance of biopolymers. However, the modulus and stiffness of biopolymers are almost similar to the traditional mineral oil-based polymers. And also the modulus of bio-based polymers can be improved by cross-linking, blending with other polymers, or plasticizing. For instance, the bacterial cellulose can be incorporated where special mechanical properties are required.
5. Compostability: it is the most critical requirement of bio-based polymers as it differentiates the biodegradable materials from recyclable materials because the composting process must change the biodegradable waste into beneficial soil products. Compostability of polymers strongly relies on characteristics of the materials. For instance, the initial step of composting is mostly the hydrolysis of polymer and hydrolysis rate depends on the water resistance and water vapor transmittance of the material. Further, the duration during which the polymer has undergone the accepted disintegration degree is called composting time. However, the complete biodegradation duration is not represented by the composting time. The composting time required for full disintegration is greatly affected by the technology used in composting. A low technology based composting, for example, passive windrow composting, usually takes more duration to acquire mature compost when compared to high technology derived tunnel composting. Moreover, particle size of polymer also influences the complete disintegration thus affecting the composting time. For instance, wood sawdust or small chips are quickly composted, while wooden logs usually disintegrate fully in a year or more (Clause, 2000).

Mechanism of Biodegradation

Biodegradation means disintegration, degradation, or loss of mechanical attributes of packaging materials using microorganisms and is progressed by hydrolysis followed by oxidation. The biodegradation rate is greatly based on the temperature (varying from 50 to 70°C), kind and amount of microorganisms, and humidity. Fast degradation is possible only if all these parameters (mentioned above) are present. Biodegradation exists quickly in the composting process where biopolymers are degraded to water, CO₂, and biomass during average 6–12 weeks (Siracusa *et al.*, 2008). The degradation can be anaerobic or aerobic in nature resulting in the formation of methane and hydrogen (biogas) in the former case and compost or sludge in the latter. Generally, the products derived from polymers biodegrade under a regulated manner. Natural biopolymers like starch, cellulose, etc. are

hydrophilic and swellable in nature in contrast to the polyolefins that are used in central packaging material and are hydrophobic in nature, exhibiting high resistance toward hydrolysis, peroxidation, and biodegradability. Prooxidants must be incorporated in polyolefins to initiate the oxobiodegradation in them. Technically, natural polymers are not suitable for food packaging due to their poor performance, which must be modified. On the other hand, the aliphatic polyesters like PLA, PHA, etc. are in between the two extremes of polyolefins and natural polymers in terms of performance, as well as biodegradability.

The oxo-biodegradation mechanism is followed in the biodegradation of natural and synthetic polymers; however, standard biodegradation needs the instant mineralization measure. Further, oxobiodegradation at room temperature is a very slow mechanism as compared to hydrobiodegradation (Scott and Wiles, 2001). According to Scott and Wiles (2001), the oxobiodegradation of carboxylic acid ($-\text{COOH}$) results in alcohol, aldehyde, and ketone molecules, which are degradable using low molar mass generated during the peroxidation that is commenced either by light or heat. This is the main reason why the hydrocarbon polymers lose their mechanical properties. After this, bioassimilation initiates by the enzymes, bacteria, or fungi resulting in the CO_2 and biomass hence producing humus. The antioxidants or stabilizers present in the synthetic polymer adversely affect the biodegradation process by inhibiting the oxidation of polymers. But these compounds are necessary to incorporate in polymer to increase the shelf-life of materials and to improve the performance also. Likewise, hydrobiodegradation is mainly employed for starch, cellulose, polyesters, etc. The aliphatic polyesters like PHBV are disintegrated and bioassimilated quickly, like cellulose and starch in an aqueous atmosphere.

Modifying the Properties of Biodegradable Packaging Materials

The biodegradable materials are associated with several major drawbacks limiting their use in the industry. Functionality of these polymers is a big issue in addition to their higher cost and availability concerns. Thermal instability, brittleness, low melt strength, high water vapor and oxygen permeability, and poor heat sealability hinder the commercial use of PLA as food packaging (Jamshidian *et al.*, 2010). Due to the hydrophilic nature of cellulose and starch materials, the water vapor transmission resistance is very low resulting in poor mechanical properties as well as stability. Other limitations include the brittleness, poor processability, and susceptibility to the degradation (Müller *et al.*, 2011). PHA/PHB films also exhibit stiffness, brittleness, poor thermal stability, and impact resistance. Therefore, great efforts are being taken to improve the functionality of biopolymers, such as:

1. Coating: it means the covering of biopolymer using a further thin film of another material. Several bio-based and non-bio-based materials can be employed as coating. For example, PLA can be layered using PCL-Si/SiO_x, PEO-Si/SiO_x (polyethylene oxide), or PLA-Si/SiO_x, which improves the barrier properties of PLA (Iotti *et al.*, 2009). Chitosan can be employed as a bio-based coating for polymers that possess poor gas barrier properties. It can be an efficient and economic technique to improve the performance of polymer. The application of coating typically improves the barrier properties, such as water vapor and oxygen permeability, grease or oil resistance, and to a little extent, the mechanical properties (elasticity).
2. Nano-based blends: nanotechnology deals with the generation and development of nanoscale (10–9 m) structures with modified and novel properties due to the high surface-to-volume ratio. In order to modify the biopolymer, there must be a healthy interaction between the nanofiller (discontinuous phase) and polymer (continuous phase), which can be achieved through polymerization, melt intercalation, and solvent intercalation. Nanoparticles, mainly nanoclays (montmorillonite and kaolinite), are preferred to improve the properties of bio-based polymers. However, it was reported that they negatively influenced the elongation at break in case of PLA films (Peelman *et al.*, 2013). On the incorporation of nanoparticles, the barrier properties are improved by the “confinement effect,” which means that the biopolymer molecules are confined between the gas molecules and dispersed nanoparticles thus presenting a tortuous way to force the water molecules. Further, the volatile compounds are slowly diffused on the degradation of nanocomposite, improving the thermal stability (Silvestre *et al.*, 2011).
3. Physical/chemical modification: physical or chemical modification of the biopolymers is another technique used for improving the polymer performance. Such kinds of modification provide a healthy effect on the barrier and mechanical properties in addition to improving the compatibility among polymers. Generally starch is modified to enhance the hydrophobicity so that they can be better compatible with other hydrophobic materials. The addition of citric acid to starch films reduces their water vapor transmission rate because carboxyl ($-\text{COOH}$) groups react with the hydroxyl ($-\text{OH}$) groups present in starch and thus decrease the free OH groups. Also, recrystallization and retrogradation are also inhibited due to the formation of strong hydrogen bonds. Further, the addition of citric acid, a cross-linking agent improves the mechanical properties of starch (Ghanbarzadeh *et al.*, 2011; Shi *et al.*, 2008). Gelatinized starch, when heated with lithium chloride (LiCl) in the presence of some organic solvent, becomes water resistant and flexible also (Fang *et al.*, 2005). Likewise, the incorporation of acetic anhydride in microfibrillar cellulose improves the hydrophobicity as well as oxygen permeability. The limited substitution of gluten with keratin (hydrolyzed) improves the barrier properties of gluten based films, which may be due to the formation of linkages between two proteins. Further, gluten film on exposure to UV irradiation formed cross-linkages within the film, enhancing the tensile strength (Peelman *et al.*, 2013).
4. Blending of other materials: the blend of two or more biopolymers seems to be of great significance provided that the polymers must be compatible with each other's features. The compatibility can be increased by adding a reactive functional group, chemical modification, or esterification. However, positive effects of blending immiscible polymers were also observed. Biopolymer cellulose can be incorporated to the bio-based polymer mainly to decrease the water vapor transmission rate and to improve the Young's modulus and tensile strength. Incorporation of starch, glycerol, or other degradable polyester into the PLA

would be beneficial in reducing the film brittleness. Chitosan film on the addition of PLA exhibited a positive effect on the barrier properties with slight reduction in the elasticity modulus and tensile strength (Cabedo *et al.*, 2006; Suyatma *et al.*, 2004).

Applications of Biodegradable Packaging Materials

The bio-based materials are mainly used to pack fresh agriculture produce, such as fruits and vegetables, fresh juices, meat, and fat rich foods. It has been observed that biopolymers have a positive effect on these mentioned products compared with traditional packages. Currently, bio-based packages are being utilized to pack products that have short shelf-life requiring low barrier properties. Commercially, PLA is widely used among several biopolymers. The bio-based packaging materials have several applications and some of them are given in Table 2.

Conclusions

Biodegradable materials are like a spell, as they can satisfy the package requirements and also do not harm the environment by breaking down into the organic matter. The biopolymers exhibit few constraints about the performance, such as mechanical and barrier properties and also cost, which can be improved by novel strategies, such as chemical or physical modifications, blending, or using nanotechniques. Biopolymers have already been used in pharmaceutical applications where functionality is more important than cost. In the food industry, these are used as biowaste bags cups, carry bags, plates and cutlery, film to pack short shelf-life food products, loose film in transport, etc. However, they are still at the beginning of commercialization. These polymers require in-depth research to improve the barrier properties and to maintain the food integrity. Further, research and development in the biodegradable polymers is the need of the hour because of humans' responsibility toward environment. That is the main driving force establishing the enormous potential of biopolymers in future.

Bioresorbable Polymers for Surgical Suture Applications

Radhika Vaid and Melissa A Pasquinelli, North Carolina State University, Raleigh, NC, United States

Martin W King, North Carolina State University, Raleigh, NC, United States and Donghua University, Shanghai, China

© 2020 Elsevier Inc. All rights reserved.

Glossary

Bioresorbable “Bioresorbable” is used interchangeably with the term “biodegradable” for polymers in the

literature. These polymers are broken down in the body into smaller moieties through hydrolytic and enzymatic degradation. They are then metabolized and finally excreted.

Introduction

A surgical suture is a biomaterial device, used for closing wounds. Sutures play a critical role in bringing and holding tissues together after injury or surgery. They promote wound healing through increasing the proximation between tissues, maintaining tension and strength across the wound until the tissue regenerates. Sutures can either be natural or synthetic. The choice for sutures is determined by the biocompatibility, the risk of infection and the mechanical requirements for the anatomical site of application. An undesirable biological response may get triggered when sutures are placed in contact with tissues which cause a severe and prolonged inflammatory reaction which delays the normal healing process. In this regard the ideal suture should have a negligible toxic or allergic reaction and ensure the environment is conducive to wound healing. Thus, a surgical suture is perfect for medical applications if it has the following characteristics (Pillai and Sharma, 2010; Balaji, 2013):

- Should be easy to handle
- Must cause minimal tissue reaction and no allergic response
- Maintain sterile conditions at the wound site by not supporting bacterial growth
- Exhibit high tensile strength and withstand tension within sutured tissues
- Must be easy to sterilize without changing the properties, such as strength and the rate of degradation
- Should have no carcinogenic or toxic effect systemically or at the site of application
- In the case of resorbable sutures, it must be absorbed after serving its function

Therefore, to promote wound healing without unprecedented failure, a suture must have adequate tensile properties and exhibit gradual degradation and resorption in body fluids, maintaining the rate of strength loss to match the rate of tissue growth. In this regard, intensive research has been undertaken in the past two decades to improve the properties and performance of surgical sutures. Additionally, sutures are the most popular mode of wound closure compared to other techniques like staples, tapes, and adhesives. This has resulted in tremendous growth in the need and use for sutures with expected market share for sutures to be USD 5.02 billion by 2023 (see “Relevant Website section”).

History of Sutures

Suturing techniques have been prevalent for more than 4000 years. They have been used since ancient times for wound closure and healing. Sutures originated and evolved in ancient Egypt and India, where linen, animal tissue, flax, hair, grass, cotton, and silk were used for closing wounds. The practice of suturing with several of these materials was cited in detail in the original Samihita, the prehistoric Indian medical literature by Sushruta, which was written in 500 BCE. Following this, other newer materials were reported by ancient physicians in Egypt, Babylon, and Greece. Advancements in suturing technology using catgut were first reported around 175 CE by Galan a physician to Roman gladiators. This resulted in the use of catgut, cotton, and silk as common suture materials until the early 20th century (Pillai and Sharma, 2010; Muffy et al., 2011). In 1869, it was a Lord Joseph Lister who developed the concept of sterilizing catgut sutures by impregnating them with chromic acid (Pillai and Sharma, 2010; Balaji, 2013). In the 1900s scientists attempted to improve the infection resistance of sutures. In this context, iodine sterilization of sutures by Claudius in 1902 became the standard sterilization method for sutures for nearly half a century (Balaji, 2013; Lupi, 2003). Until the 1930s and before the advent of synthetic materials, silk and catgut remained the most acceptable suture materials. Nylon, polypropylene, and polyethylene terephthalate (PET) in the 1940s became the predominant permanent or non-resorbable sutures, followed by the appearance of resorbable sutures in the 1960s with the discovery of polyglycolic acid (PGA). With a wide spectrum of available synthetic materials for both permanent and resorbable applications, the use of bovine catgut as a suture material has been phased out mainly because of the diseases linked to it, such as “mad cow” disease or Creutzfeldt–Jakob Disease (CJD) (Lupi, 2003; Kim et al., 2013; Devi and Vasudevan, 1985).

Fig. 1 Classification of sutures.

Classification of Sutures

Sutures are classified generally based on their source (synthetic or natural), the degradation profile and the expected lifetime in the patient's body (resorbable or permanent), and the method of construction (monofilament, twisted or braided). Since sutures are classified as a medical device, the approval for new suture materials and their manufacture comes under the regulatory control of the Food and Drug Administration (FDA). The guidelines for the suture industry and their manufacturers is set by a comprehensive collection of authoritative documents in different regions like the US Pharmacopoeia (USP), the European Pharmacopoeia (EP) and the British Pharmacopoeia (BP). The basic classification of sutures is based on their origin, i.e., collagen, synthetic resorbable, and synthetic non-resorbable. Non-resorbable or permanent sutures are further classified into three classes as follows (Pillai and Sharma, 2010; Chellamani *et al.*, 2013; King *et al.*, 2013):

- Class I – Silk or synthetic fibers of monofilament, twisted, or braided construction; where coating, if any, does not contribute to the thickness
- Class II – Cotton or linen fibers or coated natural or synthetic fibers, where coating significantly changes the thickness but does not contribute to the strength
- Class III – Monofilament or multifilament metal wire

Classification based on construction

As mentioned in Fig. 1 the construction of sutures is classified as either monofilament or multifilament. Monofilament sutures are single threads manufactured by polymer extrusion and monofilament spinning. Monofilament sutures exhibit a smooth low friction surface that provides the advantage of minimal tissue reaction and limited tissue trauma during suturing, and a reduced risk of bacterial growth compared to multifilament sutures. Owing to the single filament, it is comparatively easy to make a knot during a surgical procedure. However, there are drawbacks with monofilament sutures, such as low knot security and less flexibility, which makes the handling and formation of a small secure knot difficult. In addition, because of their filament thickness, monofilament sutures have a memory that retains the figure of 8 shape in the package, which contributes to the knotting problems. Currently monofilament sutures are made from: polyethylene terephthalate (PET or polyester), polyglycolic acid (PGA), polylactic acid (PLA), poly-4-hydroxybutyrate (P4HB), polyamide (PA or nylon), polypropylene (PP), polydioxanone (PDO) and stainless steel. Fig. 2 illustrates difference between the monofilament and multifilament sutures (Chellamani *et al.*, 2013; King *et al.*, 2013).

In contrast to a monofilament suture, multifilament sutures consist of several filaments being braided or twisted together. Polyesters, polyamides and silks are commonly used for manufacturing braided sutures, while catgut (reconstituted collagen), cotton and stainless steel are available in twisted multifilament form. Unlike monofilament sutures, multifilament sutures provide ease of handling and better knot security, since the threads exhibit high strength and high flexibility. To reduce their surface friction, a minimal amount of foreign coating material is added to the surface of the sutures while processing. Even so, their rough and uneven surface results in tissue drag, trauma and damage to surrounding tissue during suturing. This can result in the surrounding tissue experiencing injury, which is unlikely to happen with monofilament sutures.

Furthermore, the presence of microvoids within the structure of braided and twisted multifilament sutures results in the formation of microcapillaries that assist in the wicking of fluid into these void spaces. The accumulation of fluid around wounds is likely to cause the harboring of infectious microorganisms in multifilament sutures. As cited by Chu (King *et al.*, 2013), once filled with tissue exudate it is difficult for bactericidal inflammatory cells to reach these small hidden locations within the microvoids. This results in multifilament sutures being associated with infections and severe inflammatory tissue reactions, which compromise

Fig. 2 (a) Monofilament suture, (b) Braided multifilament suture (Courtesy of Ethicon Inc.), and (c) Coated multifilament suture (https://moskva.all.biz/poliefir-pletenyj-pb70140b0-m4-s-igloj-kolyushchej-g2019557#.Wi_9jt-nFPZ).

the tissues ability to defend against bacteria (Chellamani *et al.*, 2013; King *et al.*, 2013; Zhukovskii *et al.*, 2015). There has been research to address these negative issues associated with monofilament sutures. In this regard, the development of pseudo-monofilaments by Chellamani *et al.* (2013), and the coating of multifilament sutures with a thin polymer layer, as illustrated in Fig. 2. The ideal coating should be capable of eliminating the capillary action and imbibition of fluid, which fosters the bacterial growth (King *et al.*, 2013; Zhukovskii *et al.*, 2015). In addition, as can be observed in Fig. 2, sutures are manufactured in different colors by adding pigments, dyes or coatings, to facilitate their identification and improve their handling properties, particularly by making knotting easier and reducing tissue drag (King *et al.*, 2013).

Classification based on size

The USP (United States Pharmacopeia) and EP (European Pharmacopeia) are currently two standards used to classify sutures according to their size. To define the size and strength requirements of sutures, the USP standard involves a series of Arabic numbers that are either above (thicker than) or below (thinner than) zero as shown in Table 1 (Pillai and Sharma, 2010; King *et al.*, 2013; Benicewicz and Hopper, 1990; Bernhardt, 2016). So for sutures above size 0, they are denoted by a single digit such as 1, 2, 3, etc., where the greater the number, the larger the suture diameter. For sutures finer than size 0, the USP previously referred to sizes as 00 and 000. This designation has now been replaced by using a two-digit code where the first number refers to the number of 0's. As a result, a 4/0 suture is finer than 3/0 suture, and so on. On the other hand, the EP standard suture sizes are coded from 0.1 to 10 in the order of increasing diameter and decreasing fineness. The corresponding minimum diameter (mm) can be easily calculated. The EP standard provides ease of converting the code to the diameter in mm by simply dividing by 10. At the same time it should be remembered that the tensile strength of sutures is reduced by a decrease in suture diameter or an increase in fineness (Benicewicz and Hopper, 1990).

Classification based on degradation behavior inside the body

Surgical sutures are classified as (i) resorbable and (ii) permanent or non-resorbable, based on the strength loss in the stipulated time inside the human body. Resorbable sutures are reported to undergo enzymatic or hydrolytic degradation and subsequent tensile strength loss within the first 2–3 months inside the body. This is different from permanent or non-resorbable sutures, that retain their tensile strength near to the original value not only for several months, but usually for many years in vivo. These suture materials include stainless steel, polyester (polyethylene terephthalate), polytetrafluoroethylene (PTFE), nylon and polypropylene. However, silk and linen sutures are also considered “permanent” or “non-resorbable”, since they take more than 60–90 days to start their degradation process. Resorbable and non-resorbable sutures are further classified based on their polymer origin (i.e., natural and synthetic), as illustrated in Fig. 1. Details about the different polymers in these categories are given in the following section.

Non-Resorbable or Permanent Surgical Sutures

Silk is the oldest known and effective surgical suture material produced from the moth larvae of *Bombyx mori*. However, an associated protein called sericin, generates a negative biological response when placed in the human body, which raises concerns about the biocompatibility of silk. The literature reports that the reason for the incompatibility of silk in vivo have been attributed to this sericin coating. Successful removal of the sericin through a degumming process has resulted in no negative inflammatory response when the silk is used as a suture or as a scaffold for tissue engineering or other biomedical applications (Nakamura *et al.*, 1993; Das *et al.*, 2014). The major use of silk sutures is in ophthalmology, oral, dental and bladder surgery (King *et al.*, 2013; Naskar *et al.*, 2014; Koh *et al.*, 2015; Das *et al.*, 2014). In order to increase the rate of biodegradability and improve its anti-bacterial properties, research has been conducted on silk by applying a 4-hexylresorcinol (4HR) and silver coating to the sutures (De Simone *et al.*, 2014; Jo *et al.*, 2017). To provide a substitute for silk sutures, nylon monofilaments and braided nylon sutures have been developed. Both nylon 6 and nylon 66 are fabricated and used as suture materials in the United States, whereas, in view of its stiffer mechanical properties, only nylon 6 is used in Europe. Nylon sutures find applications in cataract surgery and for

Table 1 Suture classification based on size

USP size codes		EP size codes	Average suture diameter (mm)	Potential surgical applications
Naturally available resorbable materials	Nonresorbable and synthetic resorbable materials	Resorbable and nonresorbable materials	Min. Max.	
	12/0	0.01 and 0.05	0.001–0.009	Ophthalmology, microsurgery
	11/0	0.1	0.01–0.019

suturing nerves and blood vessels. Due to their inertness and ease of handling, nylon sutures are used for cosmetic surgery. Like silk, they degrade slowly over longer periods through hydrolytic degradation, which causes a slow loss in strength over time. On the other hand, polyester (polyethylene terephthalate) (PET), (polybutylene terephthalate) (PBT) and polytetrafluoroethylene (PTFE) are used for long-term applications where high tensile strength is required for the lifetime of the patient, in procedures such as the installation of a prosthetic heart valve, hernia mesh repair, and fascia and sternum closure.

Likewise, stainless steel sutures are also used for load bearing high strength applications. Next to steel and polyester, polypropylene (PP) sutures are often used, but they are difficult to handle and knot due to their high stiffness. Recently polyvinylidene fluoride (PVDF) has been developed in order to provide a long-term solution for vascular surgery, since PVDF sutures exhibit low thrombogenicity. They have similar handling characteristics to PP sutures and long-term biostability matching that of polyester (PET) (Pillai and Sharma, 2010; Chellamani *et al.*, 2013; King *et al.*, 2013).

Advantages of Resorbable Polymers for Surgical Sutures

A permanent or non-resorbable suture is resistant to biodegradation, because it becomes encapsulated in fibrous tissue, and remains encapsulated as a foreign body unless it is surgically removed or extruded. On the other hand, biodegradable polymers from both natural and synthetic origin have recently been developed with good biodegradability and biocompatibility. However, they have inherent problems that need to be discussed, and scientific and technological solutions need to be found. To address this issue, there are a number of synthetic biodegradable polymers and copolymers made from renewable resources, such as lactic acid. Currently, polylactic acid (PLA)/polyglycolic acid (PGA) co-polymers are the most widely used synthetic biodegradable materials in biomedical applications. However, there are certain limitations to PLA, such as its low hydrophilicity and slow rate of degradation, poor soft tissue compatibility, inferior physical properties, lack of processability and high cost of production. Despite PLA's increased use in medicine, it is necessary to search and develop new materials that exhibit unique properties for specific medical applications.

By using a resorbable polymer, this eliminates the need to remove the sutures after the wound has healed. Using sutures made from a resorbable polymer has the additional benefit of promoting tissue integration in the organ or body cavity following the surgical procedure. Nevertheless, the main basic reason for using a degradable polymer as an implantable device begins with the simple desire to implant a device that once it is no longer needed will not necessitate a second surgical procedure for its removal (Gomes and Reis, 2004; Papazoglou *et al.*, 2010; Sajid *et al.*, 2014; Luckachan and Pillai, 2011; Suzuki and Ikaka, 2012).

In addition to not requiring a second operation, biodegradation offers other advantages. For example, a fractured bone, fixed with a rigid, nonbiodegradable stainless steel plate, may not heal completely, and can lead to a repeated fracture upon removal of the bone plate. This happens because the load is carried by the rigid stainless-steel plate and the bone does not carry sufficient load during the healing process. This phenomenon is known as 'stress shielding'. However, a less rigid implant prepared from a biodegradable polymer can be engineered to degrade at a rate that will slowly transfer the load to the healing bone (Gomes and Reis, 2004; Papazoglou *et al.*, 2010; Sajid *et al.*, 2014; Luckachan and Pillai, 2011; Suzuki and Ikaka, 2012).

Resorbable Surgical Sutures

Catgut and Collagen Sutures

Catgut or reconstituted collagen is the most well-known natural material used for making sutures and the strings of musical instruments. It is biochemically similar to Type 1 collagen. Interestingly the term 'catgut' is completely unrelated to the feline species. Back in 1599 J.A. Murray described a 'violin, stringed instrument' as a 'cat' and hence the name 'catgut'. Collagen is the major protein component of the human body and is present in ligaments, cartilage, tendons, skin, and bone. In most cases catgut has been extracted from a bovine or porcine source, and the monofilament is referred to as either a plain and chromic type, based on the treatment that is used for its preservation. In chromic sutures, brown chrome salts are used to cross-link the collagen, which slows down their rate of absorption in the body. Catgut sutures exhibit high elasticity and tensile strength. The degradation times for losing half their strength are 7 days and 14 days for the plain and chromic sutures respectively. As a result, catgut sutures are usually used to close skin or renal incisions and wounds, where tissue regeneration occurs rapidly (Pillai and Sharma, 2010; Devi and Vasudevan, 1985; King *et al.*, 2013; Benicewicz and Hopper, 1990).

Catgut sutures are easy to handle, but their knot security is poor and their abrasive surface causes trauma to the neighboring tissues while suturing. The sutures are packaged in an alcohol solution so as to retain flexibility, and they are usually sterilized in ethylene oxide or by gamma irradiation. There have been attempts to improve the handling properties by adding a glycerine coating and avoiding the use of alcohol for packaging. The coating increases the suture thickness which raises other concerns. In addition, newer and less injurious crosslinking methods have been introduced to improve the handling and tensile properties of catgut sutures (King *et al.*, 2013; Gajjar and King, 2014).

Since catgut sutures are made from 98% collagen, they easily degrade in the body through proteolysis. In addition, collagen is thrombogenic and acts as a hemostatic agent. Therefore, catgut is generally used for closing wounds where the tissue growth is fastest. However, there are some disadvantages for catgut sutures, like an inflammatory foreign body reaction and the need for a protocol to prevent the risk of infectious disease transmission to patients. Unfortunately, regardless of these measures, some diseases, like Creutzfeldt–Jakob disease, otherwise known as 'mad cow disease', and bovine spongiform encephalopathy (BSE) have been reported to be transferred from catgut sutures to patients (Benicewicz and Hopper, 1990; Araújo and Suassuna, 2016; Barrows, 1986; Adams, 2001).

To overcome these concerns, synthetic resorbable polymers are preferable to natural polymers. In addition, synthetic polymers provide greater control over the uniformity and desired mechanical properties. Also, it is easier to predict and control the rate of degradation and loss in mechanical properties of synthetic polymers compared to those of natural origin. We will now discuss synthetic polymers used for suture applications.

Poly(Glycolic Acid) (PGA)

PGA as illustrated in Fig. 3, sometimes referred as polyglycolide, has been one of the oldest synthetic bioresorbable polymers investigated for biomedical applications. Being 45%–55% crystalline it exhibits a high tensile modulus and a low solubility in organic solvents. The glass transition temperature (T_g) of PGA ranges from 35 to 40°C and the melting point (T_m) is around 230°C. Although it has low solubility, a variety of forms and structures can be fabricated for biomedical applications. This can be done mainly through extrusion, injection and compression molding as well as by particulate leaching and solvent casting. In view of its excellent fiber forming capability, PGA have been investigated for fabricating resorbable sutures. The first PGA-based bioresorbable synthetic suture called Dexon was approved in 1969 by the United States Food and Drug Administration (FDA). In addition, non-woven PGA fabrics have been extensively used as scaffolds for tissue regeneration owing to their predictable rate of degradation, tunable mechanical properties and cell viability. PGA implants degrade by bulk erosion as a result of scission of the

Fig. 3 Repeat unit of poly(glycolic acid).

Fig. 4 Repeat unit of poly(lactic acid).

ester bonds in the polymer backbone. The suture when hydrolyzed inside the body is known to lose its strength in 1–2 months and lose its mass within 6–12 months. The main degradation products of PGA are glycine and glycolic acid, which can be metabolized by the body and excreted in urine or converted into carbon dioxide and water via the citric acid cycle. Thus, no immune or toxic response takes place. However, PGA has limited solubility, and during bulk degradation or when the rate of degradation is high, the acidic degradation products pose constraints to its use in biomedical applications. To overcome these limitations, the glycolide units are often used to synthesize copolymers (Benicewicz and Hopper, 1990, 1991; Araújo and Suassuna, 2016; Barrows, 1986; Adams, 2001; Abhari *et al.*, 2017; Bernhardt, 2016; Nair and Laurencin, 2007; Gajjar and King, 2014; Vroman and Tighzert, 2009; Ulery *et al.*, 2011; Middleton and Tipton, 2000).

Poly(Lactic Acid) (PLA)

In contrast to glycolic acid, lactic acid being a chiral molecule has two optically active forms: L-lactic acid and D-lactic acid. Poly-L-lactic acid or poly-D-lactic acid are formed after polymerization of the individual monomers and the polymers are semi-crystalline in nature (Fig. 4). L-lactide is a naturally occurring isomer and is more readily available compared to its D-lactide counterpart. However commercial polylactic acid polymer obtained from a natural source, such as Natureworks' Ingeo polymer derived from corn oil, contains both isomers with about 98% PLLA and about 2% PDLA. PLLA generally has around 37% crystallinity which is dependent on the molecular weight and processing parameters. It has a higher Tg than PGA, i.e., around 60–65°C, and its Tm is approximately 175°C. In addition, PLLA exhibits high tensile strength (~59 MPa) and high modulus (~4 GPa). PLLA is a slower degrading polymer compared to PGA. This is attributed to the presence of the voluminous methyl group present on the backbone chain that is responsible for its initial hydrophobic surface, which hinders aqueous attack. Further it has good tensile strength, low extension and a high modulus. Thus it forms a suitable candidate for implants especially in load bearing applications, such as surgical sutures and orthopedic fixtures. Some of the commercially available PLLA based orthopedic products are Phantom Suture Anchors (DePuy), Full Thread Bio Interference Screws (Arthrex) and Meniscal Stingers (Linvatec). Superior mechanical properties result in the use of PLLA in textile scaffolds for ligament replacement and augmentation devices to replace permanent fibers, such as Dacron polyester. Biomedical research continues on the use of PLA as the base material for blood vessel conduits and lipoatrophy (Araújo and Suassuna, 2016; Barrows, 1986; Adams, 2001; Abhari *et al.*, 2017; Bernhardt, 2016; Benicewicz and Hopper, 1991; Nair and Laurencin, 2007; Gajjar and King, 2014; Vroman and Tighzert, 2009; Ulery *et al.*, 2011; Middleton and Tipton, 2000; Lehtonen *et al.*, 2013).

Additionally, being more hydrophobic than PGA due to the presence of its methyl groups, PLA has a slower rate of degradation. In fact it has been observed that for high molecular weight PLA implants, they can remain from 2 to over 5 years *in vivo* before they are totally resorbed. Like PGA, the mechanism of PLA bioresorption also takes place through bulk erosion. Nevertheless, the rate of degradation depends to a large degree on the level of crystallinity as well as the porosity and thickness of the implant. Although the polymer is known to lose some of its strength and elastic modulus in the first 6 months due to the plasticizing action of water, no significant changes will occur in the mass until much later. Therefore, currently co-polymers of L-lactides or D-lactides with glycolides are being studied with the objective of developing polymers with a wider range of properties and hence increasing their scope of applications.

Polyglactin 910 or Poly(Lactide-co-Glycolide) (PLGA)

Poly(lactide-co-glycolide) (PLGA) is among the most common co-polyesters that have been investigated extensively for a multitude of applications (Fig. 5). Different ratios of poly(lactide-co-glycolides) have been researched and commercially developed to be used as resorbable fibers for biomedical applications. Panacryl is a suture on the market melt spun from a co-polymer with a higher lactide/glycolide ratio to slow down the rate of degradation. With further research, several alternative block co-polymers have subsequently been developed for the fabrication of monofilament sutures, such as poly(glycolide-co-trimethylene carbonate) and poly(glycolide-co-caprolactone) containing hard and soft segments along the polymer backbone to achieve the desired properties. Other applications include the development of tissue engineered scaffolds for skin called Dermagraft (Nair and Laurencin, 2007; Gajjar and King, 2014).

Analogous to PLA and PGA, PLGA also undergoes bulk erosion through hydrolysis of the ester bonds. In this case, besides molecular weight, shape and porosity, the degradation rate also depends on a lactide/glycolide ratio. So in the case of PLGA the ability to control the degradation rate compared to the previously mentioned homopolymers is an advantage. In addition, its

Fig. 5 Repeat unit of poly(lactide-co-glycolide).

Fig. 6 Repeat unit of polydioxanone.

biocompatibility and processability have made it a popular polymer for biomedical applications. PLGA has become a potential candidate for sutures and tissue engineering scaffolds as it promotes cell adhesion and proliferation in the process of developing healthy tissue. Several drug and protein delivery vehicles are also made from PLGA in the form of microspheres, microcapsules, nanospheres and nanofibers which are able to control their rate of release. However, due to bulk erosion of PLGA being dependent on the thickness of the material, gradual release from such drug delivery systems has been found to be problematic. Further, when used for protein release, protein denaturation occurs due to the acidic degradation products released during bulk degradation. This limitation has been overcome by using surface eroding polymers in order to achieve zero release kinetics (Benicewicz and Hopper, 1990, 1991; Araújo and Suassuna, 2016; Barrows, 1986; Adams, 2001; Abhari *et al.*, 2017; Bernhardt, 2016; Nair and Laurencin, 2007; Gajjar and King, 2014; Vroman and Tighzert, 2009; Ulery *et al.*, 2011; Middleton and Tipton, 2000).

Polydioxanone (PDO)

Bioresorbable polymers like PLA, PGA and PLGA have been successfully used to develop multifilament sutures. Recently extensive research has been undertaken to develop polymers for resorbable monofilament sutures that will replace multifilament braided sutures, reduce the potential risk of infection and lower the surface friction that causes tissue trauma when pulling the suture through soft tissue. Polydioxanone (PDO) was the material used for developing the first monofilament suture in 1980 under the trade name of PDS (Fig. 6). It has also been studied for orthopedic applications, such as the suturing of small bone and osteochondral grafts. PDO is synthesized by a ring opening polymerization of p-dioxanone. It is a colorless, semi-crystalline polymer with a low Tg ranging from -10 to 0°C , and a Tm at 106 – 115°C . PDO fibers have a low tensile modulus (1.5 GPa), and good flexibility, which can be attributed to its low Tg (Benicewicz and Hopper, 1990, 1991; Araújo and Suassuna, 2016; Barrows, 1986; Adams, 2001; Abhari *et al.*, 2017; Bernhardt, 2016; Nair and Laurencin, 2007; Gajjar and King, 2014; Vroman and Tighzert, 2009; Ulery *et al.*, 2011; Middleton and Tipton, 2000).

Degradation takes place due to non-specific scission of the ester backbone. But due to its high crystallinity ($\sim 55\%$) and hydrophobicity, PDO exhibits only a moderate rate of resorption. When implanted in the body PDO breaks into glyoxylate moieties, and is either excreted in the urine or may react with enzymes and be converted into glycine. Glycine is subsequently converted into carbon dioxide and water as in the case of PGA. Due to the slow absorption of fluid and partial degradation, the polymer is known to lose its strength within 1–2 months. Thereafter, with increased hydrolytic degradation, complete mass loss takes place within 6–12 months.

Poly(Caprolactone) (PCL)

Polycaprolactone (PCL) is a semicrystalline polymer synthesized by ring opening polymerization using a relatively cheap monomer ‘ε-caprolactone’, which makes it an attractive raw material for spinning resorbable fibers and sutures (Fig. 7). Its low Tm of 55 – 60°C and Tg of -60°C enables PCL to be easily processed. It is readily soluble in a wide range of organic solvents and forms miscible blends with a wide range of polymers. Being a polyester, it also undergoes hydrolytic degradation initiated at the water susceptible ester bond, but at a slow rate, with complete resorption taking 2–3 years. Due to its slower rate of degradation, its high permeability to many drugs and its non-toxicity, PCL is promoted as a long-term drug/vaccine delivery agent.

PCL exhibits low tensile strength (~ 23 MPa), but a high elongation at breakage, with values sometimes reaching 500% – 700% . It has also been used as a suture, but in copolymer form, because of the low strength of the homopolymer. Monocryl is a

Fig. 7 Repeat unit of polycaprolactone.

Fig. 8 Repeat unit of poly(trimethylene carbonate).

commercially available monofilament suture spun from a caprolactone and glycolide copolymer. This has resulted in less stiff and more extensible sutures compared to those made from the polyglycolide homopolymer (Benicewicz and Hopper, 1990, 1991; Araújo and Suassuna, 2016; Barrows, 1986; Adams, 2001; Abhari *et al.*, 2017; Bernhardt, 2016; Nair and Laurencin, 2007; Gajjar and King, 2014; Vroman and Tighzert, 2009; Ulery *et al.*, 2011; Middleton and Tipton, 2000).

Poly(Trimethylene Carbonate) (PTMC)

PTMC is an elastomeric aliphatic polyester with a T_g of -17°C and poor mechanical strength. However, when it is polymerized to a high molecular weight through a ring opening reaction, it has excellent flexibility (Fig. 8). In order to take advantage of these properties PTMC scaffolds have been investigated for soft tissue regeneration. At the same time low molecular weight PTMC has been investigated as a drug delivery agent. Unlike the previously described aliphatic polyesters, PTMC undergoes surface degradation and erosion, which makes it a suitable candidate as a drug delivery vehicle. The rate of degradation in the case of PTMC has been found to be higher in vivo than in vitro attributed to enzymatic degradation being experienced in vivo. Several copolymers with other cyclic lactones have been developed for PTMC. The objective of this approach is to overcome the disadvantage of its inferior mechanical properties, as this has limited its potential applications. Block co-polymers of trimethylene carbonate and glycolides have been developed and are used as a flexible suture material, namely Maxon®, and an orthopedic fixture, such as Acufex®. Additionally, a terpolymer with glycolide, dioxanone and trimethylene carbonate is commercially available and is marketed as a suture material called BioSyn® (Benicewicz and Hopper, 1990, 1991; Araújo and Suassuna, 2016; Barrows, 1986; Adams, 2001; Abhari *et al.*, 2017; Bernhardt, 2016; Nair and Laurencin, 2007; Gajjar and King, 2014; Vroman and Tighzert, 2009; Ulery *et al.*, 2011; Middleton and Tipton, 2000).

Polyhydroxyalkanoates

Polyhydroxyalkanoates, also referred to as bacterial polyesters, are naturally available bioresorbable polyesters produced from bacteria which generate the polymer as a means of storing energy. The most common bacterial polyester is poly(3-hydroxybutyrate) (P3HB) illustrated in Fig. 9(a). It was discovered in 1920, produced from the bacteria "*Bacillus megaterium*". Since then, other strains of bacteria have been found to produce other types of polyhydroxyalkanoates (Fig. 9). These polymers once extracted from their bacteria, yield a pure, semi-crystalline and isotactic structure. Like other polyesters they also undergo hydrolytic degradation at the ester bond. The mechanism involves surface erosion and follows zero order kinetics, losing the total mass in 24–30 months. The degradation products of the polyhydroxybutyrates (PHBs) are usually the monomer species, i.e., D-(-)-3-hydroxy-butyric acid, which is a normal constituent of blood. Furthermore, it melts in the range of $160\text{--}180^\circ\text{C}$, which facilitates polymer processing. In addition to bacterial synthesis, chemical synthesis routes have also been explored for PHB production. Ring opening polymerization of optically active β -butyrolactone has been used for synthesizing PHBs, which are identical to their bacterial counterpart. Copolymers of PHB and 3-hydroxyvalerate (P(HB-HV)), as illustrated in Fig. 9(c), have also been investigated. They are semi-crystalline, although they have a lower T_m , which is mainly dependent on the HV content. In addition, this copolymer features a T_g in the range of -5 to 20°C . Both PHB and P(HB-HV) have been reported to be soluble in a variety of solvents, which allows them to be processed and fabricated into various shapes, such as films, sheets, spheres and fibers.

Copolymers are comparatively less brittle and tougher than PHB homopolymers, which broadens their potential use in biomedical applications. Additionally, P(HB-HV) has a unique piezoelectric property, making it attractive for orthopedic applications, as electrical stimulation helps in bone healing. Due to its high crystallinity the degradation rate of PHB homopolymers is

Fig. 9 Repeat units of (a) poly(3-hydroxybutyrate), (b) poly(3-hydroxyvalerate), (c) poly(3-hydroxybutyrate-co-3-hydroxyvalerate), and (d) poly(4-hydroxybutyrate).

Table 2 Comparison of properties of P4HB with other aliphatic polyesters

Polymer	T_m ($^{\circ}\text{C}$)	T_g ($^{\circ}\text{C}$)	Tensile strength (MPa)	Tensile modulus (MPa)	Elongation at break (%)	Resorption time
PGA	225	35	70	6900	<3	6 weeks
PLLA	175	65	28–50	1200–2700	6	1.5–5 years
DL-PLA	Amorphous	50–53	29–35	1900–2400	6	3 months
PDO	110–115	–10 to 0	–	1.5	–	6–12 months
P3HB	180	1	36	2500	3	2 years
PCL	57	–62	23	400	700	2 years
P4HB	60	–51	50	70	1000	8–52 weeks

Martin, D.P., Williams, S.F., 2003. Medical applications of poly-4-hydroxybutyrate: A strong flexible resorbable biomaterial. *Biochemical Engineering Journal* 16 (2), 97–105. Williams, S.F., Rizk, S., Martin, D.P., 2013. Poly-4-hydroxybutyrate (P4HB): A new generation of resorbable medical devices for tissue repair and regeneration. *Biomedical Engineering* 58 (5), 1–13.

slower than that of synthetic polyesters, and complete mass loss takes around two years. However, copolymerization increases the degradation rate owing to the decrease in crystallinity. Although the relationship between the degradation profile and the HV monomer content has yet to be established, considerable research effort is focused in this direction. By increasing the rate of degradation, P(HB-HV) becomes a more attractive copolymer for use in vivo as a tissue engineering scaffold (Nair and Laurencin, 2007; Gajjar and King, 2014; Wang *et al.*, 2011; Anjum *et al.*, 2016; Bugnicourt *et al.*, 2014; Chen and Wu, 2005; Kehail *et al.*, 2017; Langer *et al.*, 2002).

In 2007 the FDA approved the use of another bacterial polyester, poly-4-hydroxybutyrate (P4HB), for the manufacture and use as a resorbable suture (Fig. 9(d)). The suture is now produced and marketed under the tradename Tephaflex® by melt-spinning the P4HB polymer. An article by Martin and Williams (2003) was the first report dedicated to presenting P4HB and its properties. However, the article focused on the commercialization and patent owned by Tephaflex Inc., and instead of describing a detailed experimental study, the paper compared the physical properties of P4HB with other polymers as illustrated in Table 2 (Suzuki and Ikaka, 2012).

Since P4HB is naturally produced from bacteria it does not contain any manufacturing additives, like catalysts and residual monomer, which can lead to post-implantation tissue inflammation. Although it is produced by bacteria, its structure is very simple and similar to that of PGA and PCL, with differences in the number of carbons in the repeat unit as illustrated in Fig. 9. The P4HB monofilament is a strong and malleable thermoplastic with similar ultimate mechanical properties, such as breaking load, to polypropylene and PDO sutures. In addition, P4HB exhibits elongation at break of 100%, resulting in a highly elastic performance. As with other PHBs, copolymerization of P4HB with other butyrates has been undertaken to enhance its mechanical or absorption properties. In addition, there have been efforts to modify the structure by functionalizing the P4HB polymer so as to produce nonacidic degradation products and improved control over the rate of degradation (Williams *et al.*, 2013; Odermatt *et al.*, 2012; Zhang *et al.*, 2013).

Preliminary studies have reported that P4HB sutures degrade more slowly than PGA and PDO sutures. However, in the study conducted by Odermatt *et al.* (2012) to assess the toxicity of the degradation byproducts of Monomax® (P4HB) sutures, it was

Fig. 10 P4HB monofilament strength retention. Adapted from reference Odermatt, E.K., Funk, L., Bargon, R., *et al.*, 2012. MonoMax suture: A new long-term resorbable monofilament suture made from poly-4-hydroxybutyrate. *International Journal of Polymer Science* 2012, 1–12.

found that they degraded more slowly in the body compared to PDS II® (PDO) sutures. On the other hand, the rate of degradation for P4HB is known to be faster than for PLLA, PCL and other PHA's *in vivo*. Recently, Williams and Odermatt have published other papers describing the suture's degradation performance in the human body and its use in other applications such as in tissue engineering scaffolds. The effect of P4HB suture size on its degradation profile is illustrated in Fig. 10.

In the last 10 years there has been an increasing number of patents related to P4HB and its applications, but few of them have discussed the fundamental concepts and mechanisms of biodegradation and bioresorption in the body. As mentioned above this biopolymer has a unique set of properties that have resulted in its introduction as a distinct new class of innovative, fiber-based commercial products for soft tissue repair. Current studies in the authors laboratory is generating information about the degradation mechanism of P4HB under various pH and enzymatic conditions. This work will help in generating the fundamental understanding that will be used for developing new biomedical applications (Williams *et al.*, 2013; Odermatt *et al.*, 2012; Williams *et al.*, 2016; Buell *et al.*, 2017).

Surgical Suture Properties

The selection of a suture by a surgeon is dependent on the required knot performance, in terms of knot strength and knot security, as well as on the anatomical environment and type of tissue it is approximating. The physical, mechanical and surface properties of the suture material will affect the suture's function, which in turn will determine the inflammatory response and the rate of wound healing.

Mechanical Properties

The mechanical properties of sutures are dependent on the polymer used and its processing conditions. It is critical to understand these properties for all polymer materials, and select only those which closely match the clinical need, the mechanical loading environment and the desired rate of wound healing. The initial and subsequent mechanical behavior of a suture comprises its strength, stiffness (resistance to stretching), viscoelasticity, coefficient of surface friction and flexural rigidity (or ease of bending), which are dependent on its thickness or diameter and its degradation profile. The mechanical properties of sutures are measured in terms of their tensile strength, modulus of elasticity, elongation at break and toughness. In addition to these general tensile properties, the knot strength and security are critical for defining the suture's functionality and *in vivo* performance. The knot strength, besides being dependent of the suture material and its processing history, is also affected by the sutures ease of bending and handling, as well as the knotting procedure, the suture size and the number of throws in the knot (Chellamani *et al.*, 2013; King *et al.*, 2013).

The tensile breaking strength of a suture is used to compare the strength of different suture materials having different sizes since it is obtained by normalizing the ultimate tensile force with respect to the suture's cross-sectional area. However, since the linear density can be measured in denier or tex more precisely for a twisted or braided multifilament suture than its cross-sectional area, it is more common in textile engineering circles to refer to the "tenacity" of a suture or yarn, rather than its tensile strength. The tenacity is calculated from the ultimate breaking force divided by the linear density measured in denier or tex, which is the mass in grams of 9000 m or 1000 m of yarn or suture respectively. The American Society for Testing & Materials (ASTM) describes the test method and test conditions for measuring, reporting and comparing the tensile properties of yarns and sutures under both dry and wet conditions.

However, one needs to refer to the U.S. Pharmacopeia in order to find the test method for measuring the tensile properties of a knotted suture. It is critical to use a suture with a tensile strength that can withstand the tension during clinical use. But equally important is the tying of a knot that will remain secure and will not fail in the patient's body during the healing period. This means that the suture needs to have high static friction on its surface so as to promote knot security. At the same time, the surface of the suture should not be rough and cause injury or trauma to the tissue it passes through. This points to the need for the suture surface to have high static friction and low dynamic friction. This apparent conflict of requirements is normally resolved with the application of suitable surface lubricants or finishes. Thus, optimal physical, tensile and surface properties are critical for sutures with respect to the anatomical location and the type of tissue they are being used to approximate (Pillai and Sharma, 2010; Chellamani *et al.*, 2013; King *et al.*, 2013; Suzuki and Ikaka, 2012).

Bending stiffness is another important mechanical attribute for a suture, which is dependent on its bending modulus. This regulates the handling characteristics of the suture in terms of ease of knotting and knot security. Suture diameter, its construction (monofilament or braided), and any treatment, like a surface coating, are the main factors determining the suture's stiffness. An increase in the bending stiffness due to increased diameter or a coating will restrict the suture's ability to bend, its pliability and ease of handling. In addition to stiffness, stretch and recovery are important properties. The amount of stretch is the ease with which the suture deforms under applied tensile stress, and the recovery is the extent to which the original form and shape is regained after the applied stress has been removed. Both these properties are significant for *in vivo* applications. Stretch and recovery play important roles when edema and swelling of the wound occurs after injury or surgery (Pillai and Sharma, 2010; Chellamani *et al.*, 2013; King *et al.*, 2013).

Handling Properties

Handling properties are those subjective attributes that the surgeon feels and experiences during the suturing process, making them difficult to quantify. However, to understand the handling of sutures, they are categorized into pliability (or stiffness), ease of knotting, knot security, package memory, surface friction, viscoelasticity and tissue drag. They are either directly or indirectly related to the physical, mechanical and surface properties as explained above. For example, the bending stiffness relates to the suture's pliability. Furthermore, the ease of handling is dependent on the coefficient of surface friction of the suturing material. This is the measure of slipperiness (i.e., low dynamic friction) which, as mentioned previously, is affected by the suture's construction and surface finish. Controlling the coefficient of friction to an optimum value is critical, because it will affect the extent of drag on the surrounding tissues and the ease with which knots can be tied in terms of the "knot tie-down" force. Drag is high when the coefficient of dynamic friction is high, resulting in trauma to the surrounding tissue. So finishes are applied to produce a more slippery surface with a lower dynamic coefficient of friction.

However, as explained earlier, making the suture smooth or reducing the static coefficient of friction will compromise the knot security. And knot security needs to be high as it is the force required to cause a knot to slip, either partially or completely, and come undone. In addition, package memory is another factor related to the flexibility and recovery of the suture. In the case where sutures exhibit package memory and remember their figure of 8 shape, handling them becomes difficult for the surgeon, as the knots tend to untie due to this memory effect. In general, monofilament sutures exhibit more package memory than braided ones. Package memory is evaluated by hanging the suture in air under a nominal load and determining the time required for the suture to straighten out (King *et al.*, 2013; Suzuki and Ikaka, 2012).

Biocompatibility

Since sutures are foreign materials in the human body, they automatically trigger an inflammatory response. The severity and duration of this response is dependent on the material, construction and size of the suture, as well as its stiffness and tension *in situ*. The anatomical environment where it is placed in the human body also has an important role to play, since it will define the pH and enzymatic activity. This biological response generated by the human body to the introduction of the suture is referred to as its "biocompatibility" (King *et al.*, 2013).

Firstly, the type of polymer from which the suture is made has a role in the tissue response. Eventually, resorbable sutures will cause less scar tissue formation due to their bioresorption over time, which is not the case for permanent or nonresorbable sutures. However, the degradation products formed in the case of bioresorbable sutures are an important factor to be considered. The degradation products like lactic acid and glycolic acid are easily metabolized by the body, although in the case of acid build up there may be a temporary negative cytotoxic tissue response. This is further governed by the environmental conditions. For example, the pH varies in different parts of the body. It is around pH 5 on the skin, while blood has a pH of 7.4. The pH reaches extreme values in the stomach and gastro-intestinal tract before and after digestion, reaching pH 3 and pH 8 respectively. Secondly, the physical properties like stiffness and hardness have significant roles to play in the tissue response. In the case of open incisions that need to be closed or when tissues are under tension, a more severe inflammatory response is generated in the surrounding tissue. In addition, the construction of a suture, i.e., whether it is monofilament or multifilament, affects the extent of wicking due to capillary action. For multifilament twisted and braided sutures the size distribution of the pores within the braid can lead to an increased risk of infection, a more severe inflammatory response, subsequent increased tissue activity and an increased risk of forming adhesions (Suzuki and Ikaka, 2012).

Design and Fabrication of Surgical Sutures

Advancements in synthetic fiber technology with the availability of an extensive range of synthetic bioresorbable polymers discussed above have opened up opportunities to harness these new polymers in the development of new suture designs. Bioresorbable polymer-based sutures exhibit a number of advantages over the non-resorbable or permanent materials. The resorption process usually provokes a healthy inflammatory response, which promotes the infiltration of cells, the formation of new blood vessels (*vasa vasorum*), the laying down of collagen and extra cellular matrix, and the generation of new tissue. This increases the rate of healing and improves the anchoring of the suture to the surrounding tissue capsule. The rate of healing occurs more slowly when permanent or non-resorbable sutures are used. In addition, the suture tension plays a critical role in this healing response, as cells behave differently when exposed to different conditions of applied stress.

Of all the bioresorbable polymers only a few can be spun into fibers and filaments for suture applications. These polymers need to have fiber forming characteristics so that they can be spun by existing melt or solution spinning technologies. The most important prerequisites for forming fibers from resorbable polymers is that they should have adequate viscosity in the melt or solution, so that they can withstand the high shear and elongational stresses in the spinline without tensile failure. In addition, the developed fibers or filaments should have an oriented and semi-crystalline structure, so they can have the desired mechanical properties and tensile performance. As stated before, not all polymers have an ability to be spun into fibers and this is primarily governed by the chemical structure of the monomer, the linear nature of the polymer chain, a high enough degree of polymerization and average molecular weight, and the ease of forming crystalline regions from the polymer melt or solution. Besides, polymers should not degrade. They should remain stable at processing temperatures and at the ambient temperature of use. The chemical structure and crystallization profile (including the rate, type and shape of the crystals) controls the extent of orientation within the fibers in the spinline during the drawing or stretching process. The degree of crystallinity and orientation have a strong influence on the mechanical properties, the absorption behavior and, most importantly, the degradation profile of the resorbable fibers. For example, interchain interactions and cross-links improve the order of the polymer structure. This leads to improved orientation and crystallinity, thus increasing the overall tensile performance and reducing the rates of hydrolytic degradation and reabsorption. By this means, bioresorbable polymers have the ability to be spun into fibers and filaments and fabricated into thin, lightweight porous textile structures that are required as tissue engineering scaffolds, drug delivery vehicles and implantable organs for the treatment of injury and disease (Gajjar and King, 2014).

Most resorbable polymers are thermoplastic. This means that they can be synthesized in the form of resin pellets and then meltspun, as illustrated in Fig. 11. Melt spinning is the most common method due to the speed of production, cost efficiency and reduced environmental impact. Here the polymer is melted in an extruder and then pumped through a filter pack and spinneret to

Fig. 11 Melt spinning process for suture manufacture.

Fig. 12 Degradation mechanisms – Bulk erosion and surface erosion.

form continuous filaments (Fig. 11). One advantage of this process is that one can spin filaments with various cross-sectional shapes, like trilobal, multilobal or hollow fibers depending on the desired application. However, in the case of sutures the shape is usually round. Additionally, bicomponent or multicomponent continuous filaments with enhanced fiber properties can also be obtained from this spinning method.

Subsequent drawing and heat setting operations are then required so as to achieve improved mechanical properties. Other modes of spinning, like solution spinning and gel spinning, are also available for spinning polymers that are not thermoplastic, or when thermally sensitive drugs need to be added to the polymer for spinning drug delivery fibers. Depending on the suture application, the filaments are spun as either monofilaments or multifilament yarns that have to be braided or twisted in a subsequent process. There are a number of processing parameters that effect the final suture properties, and hence its clinical performance. Higher processing temperatures during melt spinning which cause mechanical shear stresses may lead to premature polymer degradation. If the polymer resin is not completely dry prior to melt spinning, the rate of degradation may increase several fold due to the presence of moisture which will initiate the hydrolysis of such resorbable polymers. In addition, there may be the formation of process-induced monomer that serves as an autocatalytic initiator of the degradation process, thus increasing the rate of degradation and further impairing the mechanical properties. Also, high temperature sterilization techniques can have a significant impact on the suture degradation profile by weakening and breaking inter-molecular bonds and causing inferior mechanical product performance (Gowariker *et al.*, 1986; Gupta and Kothari, 1997).

Most importantly, controlling the rate of spinning, including the linear flow rate and the shear stresses in the spinneret is essential so as to obtain adequate crystallinity in the spun and drawn fibers. The level of crystallinity not only controls the mechanical properties, but also the rate of resorption and the degradation profile of the fibers (Ali *et al.*, 1993). Following spinning and drawing, the fabrication of suture materials involves additional processing, such as twisting and/or braiding as well as the application of finishes and coatings. In addition, commercial surgical sutures are exposed to an extensive sterilization process, which involves minimal handling. Sterilization is achieved either by a low temperature ethylene oxide treatment followed by aeration or by gamma irradiation. These procedures have been developed to prevent premature degradation or changes in the performance of the resorbable sutures while being sterilized.

Degradation Mechanism for Bioresorbable Sutures

The bioresorption time, in terms of its half-life, is an important factor used to measure the rate of degradation of a polymer inside the body. The first half-life is defined as the time required for the tensile strength to fall to half its original value. Furthermore, there is a second half-life related to the loss of mass of the suture material. This half-life is defined as the time required for the mass to reach half its original value. It is important to remember that both these half-life factors are influenced by the suture's thickness, its diffusion properties and the anatomical environment in which it is located.

Process of Bioresorption

Bioresorbable fibers are hydrolytically degradable. These fibers are made up of polymers that have chemical bonds in their backbone chain that are susceptible to aqueous attack or hydrolysis. These bonds include esters, orthoesters, anhydrides, carbonates, amides, urethanes and ureas. Bioresorption generally involves four steps in the following sequence: water absorption, loss of

molecular weight, reduction in mechanical properties, and finally the complete loss of weight or mass. The process of bioresorption starts with physicochemical hydrolysis or degradation of the polymer at pH 7.4, the normal pH for healthy whole blood. This is without any enzymes, and so it results in degradation into smaller moieties such as monomer units that are bioresorbed. When placed in the body, water and aqueous biological fluids diffuse into the material initiating the process of hydrolytic degradation. This results in a loss in mechanical performance over time. Initial hydrolysis starts in the amorphous regions of the polymer where the water and aqueous fluids can enter easily owing to a lack of interchain bonding and an amorphous structure with greater space in between the molecular chains. The entry of fluid into the polymer matrix results in an initial loss in strength and modulus since the fluid acts as a plasticizer. Thereafter, the hydrolytic degradation and breaking of bonds causes a reduction in molecular weight followed by a change in shape and disintegration. The disintegrated fragments are metabolized into oligomers, which are either absorbed or excreted by the body. Bioresorption of fibers and polymers can take place by one or more of the following mechanisms:

- (1) Solubilization (e.g., dextran, polyvinyl alcohol, and polyethylene oxide);
- (2) Ionization followed by solubilization (e.g., polyacrylic acid and polyvinyl acetate);
- (3) Enzymatically catalyzed hydrolysis (e.g., polysaccharides and polyamides); and
- (4) Simple hydrolysis (e.g., aliphatic polyesters).

Out of these four, the main mechanisms for bioresorption of implantable fibers and polymers are simple hydrolysis and enzymatically induced hydrolysis. Basically, both these mechanisms involve hydrolytic bond cleavage along the polymer backbone chain that result in fragmentation of the polymer and produces low molecular weight oligomers that are metabolized by the body (Li, 1999; Ali *et al.*, 1993).

The bioresorption process basically takes place by two alternative degradation mechanisms: (i) bulk erosion or (ii) surface erosion, as illustrated in Fig. 12. In bulk erosion, the rate of diffusion of water into the polymer structure is much faster than the rate of hydrolysis of the polymer. Due to this the hydrolysis starts from the inside and moves outwards. Thus, the shape of the polymer stays intact until there is a sudden and rapid loss in structural integrity as the polymer sample breaks open and rapidly releases its degraded material and acidic monomers into the surrounding tissue. In contrast, in surface erosion the rate of hydrolysis is faster than the rate of diffusion. As a result, the mass loss occurs at the external polymer/water interface and takes place from the outside in. As the shape diminishes over time the erosion is responsible for device thinning. The bulk integrity of the polymer is maintained throughout the degradation process. So the continuous surface erosion makes this type of polymer a suitable candidate for developing a drug delivery device.

In addition to the rate of resorption being controlled by the rate of hydrolysis of the functional groups in the backbone chain and the rate of diffusion of water inside the matrix, the polymer resorption is also governed by the thickness of the suture or polymer material. If the thickness of the material is more than the critical dimension, which is calculated for each particular polymer, then surface erosion will inevitably take place, because aqueous fluids are not able to diffuse into the polymer sample. However, if it is smaller than the critical dimension, then bulk erosion takes place. Additionally, the resorption process is made more complicated if the polymer undergoes autocatalytic degradation as is the case with PLA and PLGA scaffolds. Autocatalysis results in the generation of acidic oligomeric products like carboxylic acid, that cause a localized fall in pH and hence accelerate the degradation process. This self-catalyzed hydrolysis results in the formation of hollow structures inside fibers and polymer materials leading to a rapid deterioration in mechanical properties and a sudden loss of structural integrity. It is critical to understand this phenomenon, especially for those polymers that are used as scaffolds for tissue engineering as acidic conditions are likely to have a cytotoxic effect of cell adhesion, proliferation and growth (Gorman *et al.*, 2011; Gopferich, 1996; Tsuji, 2002; Ndazi and Karlsson, 2011; Lee *et al.*, 2014; Lee and Song, 2011) (Table 3).

Summary

Surgical sutures have been in use for more than 3000 years, witnessing during this time a multitude of research and development. From catgut to the development of synthetic bioresorbable sutures, their use and handling have been made easier for surgeons while leading to lesser traumatic conditions for patients. With new polymers being synthesized and investigated, it is important to understand both their functional properties when used as sutures as well as their ease of processing during manufacture. In order to promote the process of wound healing and make it less traumatic and pain free, further research and development is needed in the field of biomaterials for surgical sutures. This review lists the current clinical options as well as the functional properties that are expected in the future.

Introduction

In the wake of climate change, Paris Climate Accord was signed in 2015 to reduce the greenhouse gas in order to limit the global warming. Bio-waste remediation is one of the biggest challenges in reducing greenhouse gases as they tend to emit greenhouse gases (GHG), namely – CO₂, CH₄, NO_x (Schott *et al.*, 2016). In order to reduce the emission, the early open dump approach of 1960s to get rid of bio-waste changed to the current practice of integrated waste management (Hettiaratchi, 2007). One of the key aspect and undoubtedly the most prevalent and popular method of bio-waste remediation is to dump them in a landfill. However, in a landfill, the waste often undergoes anaerobic oxidation resulting in release of GHG (Chiemchaisri *et al.*, 2007; Sadasivam and Reddy, 2014). Among these GHG, it was found that CH₄, NO_x are more potent GHG in comparison to CO₂. As an example, the lifetime of CH₄ in the atmosphere is 12 years, whereas CO₂ has a lifetime of 172.9 years. However, the radiative efficiency of methane is much higher with a value of $3.7 \times 10^{-4} \text{ W m}^{-2} \text{ ppb}^{-1}$ in comparison to that of CO₂, which is $1.4 \times 10^{-5} \text{ W m}^{-2} \text{ ppb}^{-1}$ (Solomon *et al.*, 2007). Higher the radiative efficiency, higher is its warming potential per unit time. As a result of which, CH₄ warms up the atmosphere faster in comparison to CO₂. As per recent report from European commission (EU Commission, 2016), the production of methane from bio-waste decomposing in landfills, accounted for some 3% of total greenhouse gas emissions in the EU-15 in 1995. The Landfill Directive (1999/31/EC) from European Union, obliges Member States to reduce the amount of biodegradable municipal waste that they landfill to 35% by 2020.

Two of the other aspects of integrated waste management (Hettiaratchi, 2007) are recovery of energy from waste and residual waste management via recycling. However, the residual waste management via recycling seems to be energy intensive and the resulting recycled products are mostly commodity product, which makes recycling of bio-waste materials least lucrative. In fact it can be seen that while global waste management market is expected to reach \$285.0 billion by 2023 (Allied Market Research, 2018), the global biodegradable plastics, a recycled product developed from bio-waste, market is accounted for only \$2.25 billion in 2017 and is expected to reach a meager \$6.98 billion by 2026 (Report Buyer, 2018). One of the key possibilities can be development of high value nanomaterials from bio-waste materials.

While the bio-waste materials are significantly large and diverse in number, they can be broadly classified into two categories – protein and polysaccharides (Wicklein and Salazar-Alvarez, 2013). In this article, the focus will be only on three bio-waste families – cellulose and chitin/chitosan (polysaccharide); collagen (protein). While discussing about these materials, their sources, production methodologies and applications will be discussed. For all these materials two widely used nanofiber manufacturing methods, electrospinning and solution blowing will be discussed in detail. It needs to be mentioned that nanofibrillated materials obtained from the bio-wastes are also called nanofibers in literature. In order to avoid confusion, nanofibrillated materials obtained from bio-wastes will be called nanofibrils and the polymer nanofibers produced by electrospinning and solution blowing will be called nanofibers throughout the rest of the text unless mentioned otherwise.

Nanofibrillated Bio-Waste Materials

Cellulose

Cellulose is one of the world's most abundant, renewable, biodegradable and nontoxic material on earth. According to some estimates, yearly production rate of cellulose $\sim 10^{11}$ – 10^{12} tons/year (French *et al.*, 2004). This polysaccharide is the product of photosynthesis. Cellulose can be widely found in wood, hemp, bamboo, cotton, flax, algae etc. (García *et al.*, 2016). The first wide scale use of cellulose dates back 2nd century BCE China, where cellulose pulp was used to make paper. Cellulose was first discovered in mid-1800 by French chemist Anselme Payen. By late 1800s, cellulose was widely used in large scale manufacturing of high value materials celluloid, rayon etc. The most interesting part of cellulose is the hierarchy. For an example- while a tree can be as tall as ~ 100 m, the basic cellulosic structure is ~ 3 – 30 nm in diameter and 100 – 800 nm in length (Wicklein and Salazar-Alvarez, 2013). A hierarchical breakdown of cellulose is shown in Fig. 1 (Kaushik *et al.*, 2015; Thomas *et al.*, 2018). Cellulose is a linear polysaccharide composed of repeated nanometric β -1,4-linked anhydro-glucose units (AGU). These AGUs bind together via hydroxyl bonds to form larger units called microfibrils. These microfibrils then form fibrils and united fibrils form a fiber (Rol *et al.*, 2019). It needs to be mentioned that not all cellulose structures are same owing to the variety and nature of hydroxyl groups present on each AGU.

As it was mentioned in the previous paragraph, individual cellulose nanofibrils attach with each other through hydroxyl group. As a result of which, in order to produce nanostructures, be it nanofiber or nanofibrils, special emphasis is given to break the hydroxyl groups. Depending on the size and synthesis method of nanofibrils obtained from cellulose, they are broadly divided into three

Fig. 1 Hierarchical structure of cellulose from macro to nano-scale is shown here in the top. The schematic shows how using strong acid cellulose can be broken into nanocrystals. While the top corner shows SEM image of the cellulose microfibrils, the bottom corner showed the TEM images of the cellulose nanocrystals. Reproduced from Thomas, B., Raj, M.C., Athira, K.B., *et al.*, 2018. Nanocellulose, a versatile green platform: From biosources to materials and their applications. *Chemical Review* 118, 11575.

categories (Rol *et al.*, 2019) – (a) nanocrystalline cellulose (NCC) or cellulose nanocrystal (CNC) (length ~ 100 – 250 nm and diameter ~ 5 – 70 nm), (b) nanofibrillated cellulose (NFC) or microfibrillated cellulose (MFC) (length ~ 1 – 10 μm and diameter ~ 5 – 60 nm) and (c) bacterial nanocellulose (BNC) or bacterial cellulose (diameter ~ 20 – 100 nm) (Mishra *et al.*, 2019; Xue *et al.*, 2017a,b). It needs to be mentioned that throughout literature the nanofibrillated cellulose structures are called by different names, which is why at least two examples of the same material names are mentioned here. A representative SEM image of all three types of nanofibrillated cellulose is shown in Fig. 2, where Fig. 2(a–c) shows SEM images of CNC (Fortunati *et al.*, 2016), MFC (Leszczyńska *et al.*, 2018) and BC (Pötzinger *et al.*, 2019) respectively. A detailed description on the relative difference of all three types of cellulose nanofibrils are described in detail in Thomas *et al.* (2018) and Mishra *et al.* (2019). Interested reader are strongly encouraged to read these articles. However, in the following paragraphs a concise description of cellulose nanofibrils along with the cellulose based nanofibers will be provided.

Nanocrystalline cellulose (CNC)

CNCs are the smallest of the cellulose nanofibrils. As shown in Fig. 2(a), it can be seen that they have rod like structures. It needs to be mentioned that during production of CNCs, the amorphous regions are removed, which results in highly rigid and very high crystalline nanomaterial (John and Thomas, 2008). The production methods are extremely energy and/or chemical intensive. A detailed description of CNC manufacturing can be found in (Mishra *et al.*, 2019). However, one of the most wellknown method of making CNC is TEMPO-oxidation (Lorenz *et al.*, 2017). However, another very popular and high yield method is strong acid hydrolysis (Islam *et al.*, 2017; Kian *et al.*, 2018). Primarily sulfuric acid is used for acid hydrolysis. Apart from acid hydrolysis, solution plasma processing was also used (Surov *et al.*, 2018). Multiple efforts were put forward to reduce the dependence on strong acid and/or harsh chemical (Chowdhury and Abd Hamid, 2016; Cui *et al.*, 2016). However, still there hasn't been significant improvement in order to create a true "green" process, which is scalable industrially.

Fig. 2 SEM images of (a) CNC (b) MFC and (c) BC are shown. Reproduced from (a) Fortunati, E., Luzi, F., Jiménez, A., *et al.*, 2016. Revalorization of sunflower stalks as novel sources of cellulose nanofibrils and nanocrystals and their effect on wheat gluten bionanocomposite properties. *Carbohydrate Polymers* 149, 357. (b) Leszczyńska, A., Stafin, K., Pagacz, J., *et al.*, 2018. The effect of surface modification of microfibrillated cellulose (MFC) by acid chlorides on the structural and thermomechanical properties of biopolyamide 4.10 nanocomposites. *Industrial Crops and Products* 116, 97. (c) Pöttinger, Y., Rahnfeld, L., Kralisch, D., *et al.*, 2019. Immobilization of plasmids in bacterial nanocellulose as gene activated matrix. *Carbohydrate Polymers* 209, 62.

Owing to the size and chemical properties, CNCs have wide range of applications. CNCs have been used for heavy metal removal (Khoo *et al.*, 2018). CNC was used as an excellent templating material to create nanostructured material to create extremely active catalytic material (Xue *et al.*, 2017a,b; Chen *et al.*, 2017). CNC was also shown to create extremely transparent film in conjunction with guar gum with excellent oxygen barrier properties (Cheng *et al.*, 2015). Owing to the strong hydrogen bonds of CNC, it was shown to act as a potent reinforcing material to create extremely strong materials with excellent barrier properties (Cha *et al.*, 2014; Xu *et al.*, 2013; Wang *et al.*, 2015). CNC was also used antibacterial material, aerogel materials and other high value composites (Tavakolian *et al.*, 2018; De France *et al.*, 2017; Shi *et al.*, 2013; Kaushik and Moores, 2016).

Microfibrillated cellulose (MFC)

Microfibrillated cellulose or MFC is intrinsically long cellulose nanofiber. They are much longer than CNCs. In fact unlike CNCs, MFC has amorphous region attached to it resulting in longer structure with various shapes starting from cylindrical to flat ribbon like structure as seen in Fig. 2(b) (Li *et al.*, 2017). The production method of MFCs are less chemical intensive than that of CNCs. However, MFC production requires lot of mechanical energy. MFCs can be prepared via a plethora of processes. A detailed yet concise description can be found in Rol *et al.* (2019). Irrespective of the processes and specifics, the basic mechanism of producing MFC is the following. The pulp or the stock solution is subjected to very high shear force and impact force, resulting in cellulose nanofibrillation. This results in MFC. This process of nanofibrillation can be achieved via homogenizer, extruder, grinder, ultrasonicator, microfluidizer, ball mill, cryocrusher and other methods (Dinand *et al.*, 1999; Zimmermann *et al.*, 2004; Nair *et al.*, 2014; Ho *et al.*, 2014; Deng *et al.*, 2016; Dufresne *et al.*, 1997; Boufi and Chaker, 2016). Although in comparison to CNC manufacturing, these processes are relatively “greener”, they require lot of energy and the yield is pretty low. However, presently there had been commercially available process, where the pulp is mixed with abrasive and inexpensive inorganic particles. Upon grinding these particles accentuate shear and impact force resulting in MFC at a lower energy (Fiberlean, 2018). However, the process results in MFC with many unwanted inorganic particles.

MFC were used in creating silver nanowire based transparent conductive film, where the MFC was used to improve film adhesion, homogeneity and ageing (Hoeng *et al.*, 2016). MFC are widely studied in wound healing and biomedical purposes (Dumanli, 2017; Xue *et al.*, 2017a,b). MFC on being functionalized by nanoparticles and other starting from noble metals to inorganic and organic chemicals shows significant promise as antibacterial material, which in turn can be used for drug carrier, wound dressing and packaging material (Li *et al.*, 2018). Owing to high number of hydrogen bond sites, MFC is used to make functional nanocomposites, paper manufacturing and barrier material, which holds the potential for large scale manufacturing (Lavoine *et al.*, 2012; Siró and Plackett, 2010; Boufi *et al.*, 2016; Liu *et al.*, 2011; Morits *et al.*, 2017).

Bacterial nanocellulose (BC)

BC is the cellulose created by some species of bacteria. BC was first discovered in 1886 (Brown, 1886), where it was found that BC was synthesized by *Acetobacter xylinum*, an acetic acid bacteria, under aerobic condition. In this work, the author found that the bacteria synthesize cellulose using glucose as carbon source. As the field progressed, it was found that BC can be synthesized by different bacteria species, namely – *Gluconoacetobacter xylinus*, *Agrobacterium*, *Pseudomonas*, *Rhizobium*, and *Sarcina* using culture media containing glucose, phosphate, carbon, and nitrogen sources (Klemm *et al.*, 2011; Bodin *et al.*, 2007; El-Saied *et al.*, 2004). As BC is a byproduct of biosynthesis, the morphology, size etc can be controlled via varying incubation conditions, namely – oxygen ratio, bacterial strain, nutrient type, carbon source and incubation time. BC is very pure and mainly composed of α -cellulose. BC has a characteristic ribbon-like nanofibril structure (cf. Fig. 2(c)) with high degree of crystallinity (Czaja *et al.*, 2004) and requires no mechanical energy and harsh chemicals unlike other cellulose nanofibrils. However, it needs to be mentioned that the output of BC is

significantly low in comparison to CNC and MFC making it extremely expensive and thus limiting its uses. However, there has been some commercial applications, where BC is used as commercially available wound dressing material for periodontal diseases reconstruction (Farah, 1990).

BC is an excellent nanomaterials as the fibrils are straight and have very little polydispersity from the viewpoint of their dimension. Additionally, the BC fibrils have higher percentage of crystallinity resulting in very high elastic modulus ~ 78 GPa (Thomas *et al.*, 2018). It was also found out that BC is hydrophilic in nature with the capability holding large amount of water and interpenetrating structure with pore size comparable with that of cell (Klemm *et al.*, 2006; Thomas *et al.*, 2018). However, as it was mentioned, BC output is extremely low resulting in higher cost of making BC en masse. As a result of which, in spite of superior properties, BC application is limited to biomedical application. A detailed description of application of BC as biomedical nanomaterial can be found in Barud *et al.* (2016). In a nutshell, BC was used as wound dressing material for burnt victims (Fontana *et al.*, 1990). Following the work of Fontana significant effort was put forward to use BC as wound healing material, where it was found that BC reduces healing time (Czaja *et al.*, 2007). In this work, the authors hypothesized that the healing results for capture of ions via hydrogen bond resulting in efficient execution of healing pathway like skin. BC based system was also used controlled drug delivery (Alkhatib *et al.*, 2017; Wang *et al.*, 2011). Owing to the repeating structure, controlled porosity and ability to soak large amount of water BC is widely used as main constituent in scaffolding material (Bäkdahl *et al.*, 2008). In order to produce ideal scaffolding material several techniques were used, e.g., sacrificial matrix, freeze drying etc (Bäkdahl *et al.*, 2006; Gao *et al.*, 2011). Owing to its superior hydrogen bond, BC based ultrafilters are also used for ultrafiltration (Xu *et al.*, 2018).

Chitin

Chitin is the second most abundant biopolymer in the world with a production rate $\sim 10^{10}$ – 10^{11} ton/year (Gopalan and Dufresne, 2003). It also one of the most wasted biopolymers. Chitin is mainly found in the exoskeletons and cell walls of crustaceans (e.g., shrimp, crab, lobsters etc), insects, arthropods, mushroom, certain variant of fungi to name a few. It is polysaccharide in chemical nature. Chemically it is almost similar to cellulose. It is known to be cellulose analogues with a (1,4)- β -N-acetyl glycosaminoglycan-repeating structure (Fig. 3). In order to solubilize in water, chitin is deacetylated to produce Chitosan, whose chemical structure is also similar to cellulose and chitin as shown in Fig. 3. Chitin is a semicrystalline biopolymer. It mainly consists of nanofiber, which are ~ 10 – 50 nm in diameter and 300 nm in length being embedded in protein matrix. Owing to its linear structure with two hydroxyl groups and an acetamide group, antiparallel chitin nanofibrils are arranged in a highly crystalline fashion with strong hydrogen bonding having high binding energy (Raabe *et al.*, 2006; Chen *et al.*, 2008; Giraud-guille, 1984; Raabe *et al.*, 2005). High crystallinity coupled with high aspect ratio and excellent material properties position chitin nanofibril as a potent nanomaterial. It needs to be mentioned that as chitin nanofibril can be obtained from variety of sources, depending on the source, chitin nanofibril dimensions can be drastically different (from tens of nanometer to micron range). However, in spite of excellent properties, most chitin is thrown away as industrial waste, which provides us a significant opportunity to create a high value nanomaterial.

Fig. 3 Schematic of hierarchical organization of Chitin from crab shell to nanofibril structure is shown. On the left hand side the generic molecular structure of chitin, chitosan and cellulose is shown emphasizing the basic similarity in structure. On the right hand side SEM image of chitin nanofibril is shown. Reproduced from Ifuku, S., Saimoto, H., 2012. Chitin nanofibers: Preparations, modifications, and applications. Nanoscale 4, 3308.

Owing to the similarity in structure between chitin and cellulose, the extraction of chitin nanofibril are quite similar and follow almost similar protocol as described for CNC and MFC (Lin *et al.*, 2012). The basic method of extraction varies from mechanical shearing and impact to grinding to enzymatic-mediated production to ionic liquid preparation to combine mechanical shearing or grinding with chemical processes (Lin *et al.*, 2012). In Ifuku and Saimoto (2012) authors produced chitin nanofibers from crabs, prawns and mushroom by a simple mechanical treatment (a grinder, a Star Burst atomization system, and a high speed blender) after the removal of proteins and minerals. They subsequently washed the raw materials by HCl and NaOH successively. They found that mechanical treatment under acidic conditions facilitate fibrillation of Chitin. In Kadokawa *et al.* (2011) the authors soaked crab shell in ionic liquid, 1-allyl-3-methylimidazolium bromide (AMIMBr). This results in swelling of chitin. Then they heated the swollen structure at 100°C, which resulted in a gel. Then the gel was soaked in methanol and sonicated to a chitin nanofibrils were obtained.

Chitin nanofibril has excess positive charge on its surface (Feng *et al.*, 2018). This intrinsically makes nanofibrillated chitin an ideal candidate for creating nanocomposites. Cellulose nanofibril on the other hand are intrinsically negatively charged on the surface. This results in successful creation of transparent film composed of chitin and cellulose nanofibrils (Feng *et al.*, 2018). Owing to surface charge and strong mechanical properties, nanofibrillated chitin was mixed as a reinforcing agent with negatively charged PEO to create polymer electrolyte film, which can be used in Li-ion battery (Azizi Samir *et al.*, 2004, 2005). Chitin nanofibril grafted with PCL have also been directly thermoformed and injection molded to create strong and sustainable polymer composite (Xu *et al.*, 2008). In another work (Fadaie and Mirzaei, 2018), the authors showed polymer film created with PCL and chitin nanofibril showed better mechanical strength along with improved cell viability making such composite a suitable candidate for making scaffold. Chitin nanofibril was freeze dried to create highly porous aerogel with abundant acetyl amino groups ($-\text{NHCOCH}_3$) on the surface followed by surface grafting of Ag_2O , which showed high iodine capture efficiency (Gao *et al.*, 2017). Lin *et al.* (2011) developed a pH-sensitive microsphere based controlled release system for drug delivery using CNC, chitin nanofibrils and platelet-like starch nanocrystals integrated in a, alginate-based microspheres. These microspheres, containing interpenetrating structure of polysaccharides, loaded with drug were able to inhibit burst release of drugs.

Collagen

Collagen is the most abundant protein in most mammals. It is the basic building block of mammals particularly in tendons, bones, skin, corneas, and cartilage. The name collagen stems from Greek, which means “glue forming” compound. In fact in earlier days, it was used to produce glue. Collagen serves multiple function in mammal’s bodies ranging from scaffolding, morphogenesis and repair. It is the basic building block of bones, which acts as load bearing unit. It creates linkage between different parts of the body to smoothly transfer the load and also store excess energy. In a nutshell, collagen provides strength, fracture resistance capability along with flexibility. Such versatility of collagen can be attributed to its complex hierarchical structure. From its polypeptide sequence, multiple (>28) distinct collagens are identified (Pauxkandle *et al.*, 2002) and can be broadly classified into: (i) fibril forming collagen; (ii) fibril-associated collagens with interrupted triple helices (FACITs); (iii) network-forming collagens; (iv) transmembrane collagens; (v) endostatin-producing collagens; (vi) anchoring fibrils; and (vii) beaded-filament-forming collagens (Kadler *et al.*, 2007; Neel *et al.*, 2013). However, the major collagen is the fibril forming collagen, termed as collagen I and this type of collagen is of interest in this chapter.

Collagen I are generally made up from combinations of 10 polypeptide chains, denoted by $\alpha 1(\text{I})$, $\alpha 2(\text{I})$, $\alpha 1(\text{II})$, $\alpha 1(\text{III})$, $\alpha 1(\text{V})$, $\alpha 1(\text{V})$, $\alpha 3(\text{V})$, $\alpha 1(\text{XI})$, $\alpha 2(\text{XI})$ and $\alpha 3(\text{XI})$ (Neel *et al.*, 2013). Irrespective of the polypeptide chains, these chain consists of amino acid triplets- glycine-proline- hydroxyproline (termed as Gly-X-Y). Although this primary structure is well studied, there can be variation owing to post-translational modification. The collagen fibrils diameter ~ 100 nm and length ~ 1 μm (Fig. 4). Collagen

Fig. 4 TEM images of collagen I. Reproduced from Wicklein, B., Salazar-Alvarez, G.J., 2013 A functional hybrids based on biogenic nanofibrils and inorganic nanomaterials. *Materials Chemistry* 1, 5469.

nanofibrils are obtained from variety of natural sources namely- chicken, kangaroo tail, rat tail tendons, duck feet, equine tendon, alligators bon/skin, bird's feet, sheepskin etc. (Rodriguez *et al.*, 2018). Apart from natural sources, collagen is also manufactured synthetically by using 36 amino acids that self-assemble into triple-helix nanofibril structure (Kumar *et al.*, 2014). This synthetic collagen nanofibril is called KOD and it eliminates the variability that stem from collagen nanofibril and results in higher yield.

Owing to its price point and difficulty in manufacturing collagen nanofibril is primarily limited to biological and cosmetics application. It is used as a bio-active filler in dental fillers (Breschia *et al.*, 2018). It is used to create membranes for guided tissue regeneration as the matrix helps to organise the cells in space and provides attachment (Khan *et al.*, 2011). Collagen scaffolds formed by various methods (Neel *et al.*, 2013) were used for various medical purposes ranging from neural to bladder repair to skin substitute to ligament and tendon repair. A detailed discussion about how collagen based medical solution improved patient healing can be found in Neel *et al.* (2013). Collagen was also used to make nanocomposite to create artificial bone, where Collagen was mixed with different inorganic material, namely-hydroxyapatite, calcium phosphate etc. to engineer bone tissue (Kuttappan *et al.*, 2016). Based on this ideology, commercial products are already available in market, e.g., Bio-Oss Collagen®, GingivAid®, CopiOs Sponge and Paste, Puros® DBM Putty, INFUSE® Bone Graft, Vitoss® etc. Owing to high biocompatibility and ability to retain water collagen nanofibril based cosmetic products are widely used and promoted (Rodriguez *et al.*, 2018).

Continuous Nanofiber Manufacturing Techniques

As it can be seen, nanofibril obtained from bio-waste materials require significant amount of harsh chemical and/or energy treatment. Additionally it requires, lot of post processing in order to use the bio-waste based nanofibril. Another big challenge is that the yield in almost all the cases is extremely low making the nanofibril production methods economically expensive. This poses the question if it is possible to create bio-waste based nanofiber structures en masse. Electrospinning and solution blowing are two processes that allow us to create bio-waste based nanofiber system en masse. In this section basics of electrospinning and solution blowing will be provided. Following that some of the key examples of making nanofibers from bio-waste material will be provided along with some applications

Electrospinning

Electrospinning is the process of making nanofibers via electrohydrodynamic process. During electrospinning process, polymer solution of sufficient viscoelasticity is supplied through a nozzle, which is then subjected to electric field ($\sim 1\text{--}2\text{ kV/cm}$) and the final product is collected at the ground electrode, which is situated at 10–15 cm distance from the nozzle. Schematic of electrospinning is shown in Fig. 1. Electrospinning is capable of producing nanofibers with diameter $\sim 100\text{--}500\text{ nm}$ (Doshi and Reneker, 1995; Reneker *et al.*, 2000; Reneker and Yarin, 2008). Apart from needle based electrospinning, there have also been for needle less electrospinning (Yarin and Zussman, 2004; Elmarco, 2019). However, the principle of manufacturing nanofibers remain the same. Although electrospinning is a matured technology today, the first record of electricity mediated hydrodynamic process dates back to 16th Century, observed by William Gilbert and later in 1750 by French physicist Jean-Antoine Nollet. Later, the theoretical background of electrohydrodynamic process describing electrospinning was described by Rayleigh (1882) and in 1960s by Taylor (1964, 1966, 1969). Although significant focus generated around electrospinning in 1990s following research work by Doshi and Reneker (1995), according to Filatov *et al.* (2007), former Soviet Union secretly made significant progress in electrospinning in 1950s with primary focus towards interception of fragments generated by nuclear bomb (Sinha-Ray, 2018).

In the seminal work, by Dr. Reneker and Dr. Yarin's group in 2000s (Reneker *et al.*, 2000; Reneker and Yarin, 2008), theoretical models describing in electrospinning in detail was developed supplemented by experimental observation. The readers interested in the theoretical description of electrospinning are highly encouraged to read these works. For the sake of brevity, in this work, only the underlying mechanism will be described. During electrospinning (cf. Fig. 5), the polymer solution is subjected high electric field. Owing to this electric field near the nozzle a conical shaped meniscus of polymer solution is formed. This is called "Taylor cone". In this zone the characteristic time of charge relaxation (τ_c) is way smaller than characteristic time of hydrodynamic residence (τ_H). As a result of which in the Taylor cone polymer solution behaves as conductor and the charge remains on the surface and the polymer jet initiates. In the polymer jet domain τ_c/τ_H increases significantly. As a result of in this domain charged polymer jet behaves as dielectric and the charge resides inside the jet. In this way, during both of these two electrohydrodynamic processes, polymer solution behaves as leaky dielectric. In this jet mode, small perturbation increases exponentially owing repulsion caused neighbouring charge as shown in Fig. 5(b). This results in vigorous bending and flapping of polymer jet. If the polymer jet has required viscoelasticity, it stretches and solvent evaporates during the vigorous bending and flapping and within a distance $\sim 10\text{ cm}$ from the needle exit, liquid polymer jet of diameter $\sim 1\text{ mm}$ turns into solid polymer nanofiber of diameter $\sim 100\text{--}500\text{ nm}$. The beauty of electrospinning is that polymer nanofiber is being created at room temperature. As a result of which bio-waste materials, which in most of the cases are temperature sensitive, can be turned into nanomaterials. In addition to that such nanofiber making doesn't require "clean room" type condition, which is typically required for production of nanomaterials, which makes this process cost-effective.

Brief introduction to solution blowing

Unlike electrospinning, solution blowing is relatively new process to make nanofibers. The process was reported around the same time by two independent groups (Medeiros *et al.*, 2009; Sinha-Ray *et al.*, 2010). Since then, significant work has been done to create monolithic and core-shell soy-protein containing nanofibrous nonwovens (Yarin *et al.*, 2014; Sinha-Ray *et al.*, 2015, 2011; Khansari *et al.*, 2012; Sinha-Ray *et al.*, 2012; Zhang *et al.*, 2013; Khansari *et al.*, 2013b) as shown in Fig. 6(a), where the solution

Fig. 5 Schematic for electrospinning. In panel (a) in the inset representative image of the electrospun nanofiber. Panel (b) shows the schematic for the jet initiation and bending resulting in nanofibers and nanoparticles. Reproduced from (a) Zupancic, S., Sinha-Ray, S., Sinha-Ray, S., *et al.*, 2016. Controlled release of ciprofloxacin from core-shell nanofibers with monolithic or blended core. *Molecular Pharmaceutics* 13, 1393.

blowing die and the lab-scale process is shown. The basic working principle of solution blowing is also shown in the inset of Fig. 6(a) (Kolbasov *et al.*, 2016). In a typical solution blowing process the polymer solution is delivered from a syringe pump at a rate $\sim 5 \text{ mL/h}$ to a reservoir attached to the core nozzle. Air is supplied through the concentric nozzle at the pressure of 3–5 bar from a high pressure line. Polymer solution from the reservoir is issued into the surrounding high-speed air jet flow (the gas jet has velocity in the 150–200 m/s range). The gas jet accelerates and stretches the core polymer jet. The latter possesses a short ($\sim 1 \text{ mm}$) straight part followed by a large-scale part which undergoes not only stretching but also a substantial bending instability, i.e., flapping. Stretching and bending instability result in significant thinning of the polymer solution jet, while solvent is gradually evaporating. At a certain stage, polymer precipitates, nanofibers solidify, and are collected on a solid grid-like collector, or on a wide rotating wheel. SEM images of solution blown monolithic PAN nanofibers are shown in Fig. 6(b) and (c). It can be seen that the nanofiber diameter range is within 150–250 nm and the individual nanofibers are quite uniform in the longitudinal direction (Sinha-Ray *et al.*, 2010).

Fig. 6 (a) Schematic of a single-needle setup for solution blowing of monolithic nanofiber mats. In the inset in panel (a), an actual single-needle die and schematic of the solution blowing process are shown. SEM image of solution blown nanofiber is shown in panel (b) and (c). Reproduced from (a) Kolbasov, A., Sinha-Ray, S., Joojode, A., *et al.*, 2016. Industrial-scale solution blowing of soy protein nanofibers. *Industrial & Engineering Chemistry Research* 55, 323. (b, c) Sinha-Ray, S., Yarin, A.L., Pourdeyhyimi, B., 2010. The production of 100/400 nm inner/outer diameter carbon tubes by solution blowing and carbonization of core-shell nanofibers. *Carbon* 48, 3575.

Following the same principle and design criteria developed for a single-needle die described in the previous paragraph, an industrial scale up process is described in Kolbasov *et al.* (2016), which uses concentric air nozzles. The schematic of the experimental setup used in the industrial-scale solution blowing is shown in Fig. 7(a). Polymer solution was poured into the hopper and by gravity fed into a positive-displacement gear pump. The flow rate was controlled by adjusting the angular speed of the gear pump with 1 RPM corresponding to 10 mL/min. The pump speeds in the range 0.5–3 RPM were used in the experiment. From the pump, solution was supplied into a redistribution chamber and then to the spinneret. The spinneret consisted of an array of concentric annular nozzles with 41 nozzles per row and 8 rows (Fig. 7(b)). The solution was discharged through the inner nozzles into a high temperature, high-speed air jet issued from the outer nozzles. The air temperature was controlled by the output of an electrical heater. A representative solution blown mat using Biax die is shown in Fig. 7(c), whereas Fig. 7(d) shows the SEM images of the fiber mat showing that significant amount of fibers are submicron in diameter. This work clearly demonstrates the ability of solution blowing process to produce nanofibers en masse.

Electrospun and solution blown nanofibers and their applications

Electrospinning and solution blowing provides the avenue for producing bio-waste based nanofiber mat with a high yield, where solution blowing holds the potential to produce nanofiber mats at industrial scale. This provides significant opportunity for turning bio-waste materials into a high value nanomaterial. Irrespective of the process, the basic idea is the following. Most of the bio-waste materials can't be spun by itself owing to their low viscoelasticity. To add additional viscoelasticity the materials are

Fig. 7 (a) Schematic of the industrial-scale solution blowing setup used in the experiments. (b) An actual multi-nozzle solution blowing process using Biax die nose-piece. It consists of 41 nozzles per row and 8 rows. (c) A sample of soy protein isolate and PEO based nanofiber mat is shown, (d) SEM image of the nanofiber mat is shown here. In this work, no special measures for vapor removal were taken, since only aqueous solutions were used. Reproduced from Kolbasov, A., Sinha-Ray, S., Jiojode, A., *et al.*, 2016. Industrial-scale solution blowing of soy protein nanofibers. *Industrial & Engineering Chemistry Research* 55, 323.

dissolved in a host polymer solution, where the polymer and the bio-waste materials are dissolved in a common solvent. The resultant solution is then spun. Significant work has been done in creating electrospun nanofiber from cellulose and chitin (Min *et al.*, 2004; Ohkawa *et al.*, 2004; Subramanian *et al.*, 2004; Noh *et al.*, 2006; Khil *et al.*, 2005; Liu and Hsieh, 2002; Son *et al.*, 2004). The electrospun bio-waste based nanofiber mats were used for controlled drug delivery, cell growth, separator for Li-ion battery etc. (Zupancic *et al.*, 2016; Sheng *et al.*, 2017; Jayakumar *et al.*, 2010). However, the idea of utilizing bio-waste to make nanofiber got significant push, when it was first shown it is possible to produce soy protein based nanofiber mat with very high loading of soy protein isolate (Sinha-Ray *et al.*, 2011). This work was motivated by the fact that USA is world's one of the largest soy producer. Soy is used to produce biodiesel and the remnant material, soy protein, is dumped resulting in greenhouse gas emission. This work was the first significant progress towards developing soy based nanofiber mat that can be produced at scale at a significantly lower cost. Such produced soy based nanofiber mats were tested for their strength (Khansari *et al.*, 2012). It was found that these soy protein nanofiber mats were as strong as host polymer nanofiber mats. These soy protein based solution blown nanofiber mats were loaded with model drugs and it was shown that as soy protein leaches out over time, these nanofiber mats can be used to control burst release of drugs, which is otherwise prevalent in other nanofiber based drug delivery system (Khansari *et al.*, 2013a,b). The soy protein based nanofiber mats were decorated with silver nanoparticles, which showed significant antibacterial activity (Zhang *et al.*, 2013). Both of these two works show that the soy protein based nanofiber mats hold the potential to be antibacterial nanomaterial with the ability of controlled drug release that can promote wound healing. The idea of making solution blown nanofiber mat was extended with bio-waste based materials, namely – zein, lignin, cellulose acetate, silk protein (sericin) and bovine serum albumin (Khansari *et al.*, 2013a,b). These nanofiber mats showed that they can be physically and chemically crosslinked in order to produce strong nanofiber mat with pore size $\sim 10 \mu\text{m}$ thus opening the possibility of

making packaging material with superior barrier properties. Similarly, bio-waste based nanofiber mats were also used as a filter for heavy metal from water effectively owing to their active surface moieties (Kolbasov *et al.*, 2017).

Conclusion

Famous English poet William Wordsworth once wrote, “*Come forth into the light of things, let Nature be your teacher*”. Bio-waste based nanomaterials hold similar key to a lot of problems starting from mitigation of greenhouse gas to advanced healthcare to energy storage to packaging materials and other application. In this article, a brief overview has been provided to understanding the present status of bio-waste based nanofiber materials ranging from sources to preparation method to applications. However, as it can be seen from the nanofibrils that the biggest challenge is that their yield is low despite being extremely high power and chemical dependent. Electrospinning and solution blowing reduces the yield problem but the challenge is that most of the chemical needed to prepare the solutions are harsh and it requires sophisticated solvent capturing method for making these processes low on harsh chemical footprint. So, there is a huge potential and opportunity for researchers to make a positive impact by creating improved processes by developing “Green Solvent”, low power processing condition etc. Another challenge is to create mass awareness around the perils of wasting bio-waste materials. In this way, the future interdisciplinary research potential is huge, where chemists, process engineers, economists, social scientists and policy makers can work in tandem to create a true green process. Borrowing from famous poet, Robert Frost, “miles to go before we (researchers) sleep” to truly create ubiquitous and impactful bio-waste based nanofiber materials.

Introduction

The biobased products have explored potential all over the world due to green globalization regarding the environmental hazard linked to synthetic products. Now researchers are giving emphasis on the sustainability as they are giving importance to the biobased products whose raw materials are biodegradable. Clearly, biodegradable materials are disintegrated naturally and do not hamper the eco-system, hence the environmental sustainability is maintained. Sustainability means full-filling the present need without hampering the future (Shahinur and Ullah, 2017). Indeed nature is the source of all biobased materials, which are mainly collected from minerals, plants, and animals. Bio-products mean bio-fuels, organic chemicals, bioenergy, material and composites, intermediary biochemical and biomaterial, and other bioproducts. In this particular article, the biobased fiber product will be emphasized. Bio-based materials namely, fibers, can be particles, chopped as well as long form in the biobased-composites or products.

Based on the different sources, biobased-materials can be categorized. For example, jute, banana, and kenaf, are categorized as bast fiber; coir, cotton, piassava, and date palm are fruits fiber; sisal, abaca, pineapple are leaves fiber; bagasse and bamboo are grass fiber; rice, wheat, barley, and maize are stalk fiber; wood, silk, sheep wool, eggshell, and hair are animal fiber; whereas asbestos is mineral fiber. Biobased materials are collected from nature and have a positive impact on the eco-system as shown in Fig. 1.

Biobased products are made from the above-mentioned biobased sources. After use of a biobased-product in the artificial world, it is disposed in nature or recycled as shown in Fig. 1. From Fig. 1 it is clear that if biobased-material is consumed in the product, the eco-system will not be affected. That means sustainability can be maintained. One important part of the biobased product life cycle is product design and development. A product, namely, headphone has different components such as frame, speaker, rubber, connecting wire and foam. Suppose, a manufacturer will produce a product such as frame of the headphone which has specific shape, which performs a function, which is made of a material or group of materials and which is a system or part of a system (as shown in Fig. 2). To manufacture this component of the headphone, one needs to design that component having a specific shape that will perform a particular function and that will be made of cheap, good quality, and widely available materials. Furthermore, this component will be a part of headphone as shown in Fig. 2. Among these four issues as mentioned before, material selection is an important one. If the selection of material is biobased material for the frame, the headphone will be lighter (as biobased materials have low density), partially biodegradable, as well as the energy consumption due to manufacturing and transportation, will be less.

In this article, the biobased material particularly, biobased-fiber, for biobased product development has been considered due to light weight. Let us consider the case of a vehicle. In the vehicle, 75% fuel cost is paid due to heavyweight. A lightweight vehicle is possible if we go through the biobased composite for vehicle component. Biobased composites simply made of these types of biobased materials are 50% lighter compared to the glass composite as natural fibers, as well as biobased materials have low density. Despite having some limitations of the biobased products such as progressive moisture absorption, less fire resistance, microbe infection, low temperature limitations, and poor mechanical properties, most importantly, the price variations during

Fig. 1 Biobased product development and life cycle.

Fig. 2 Different elements of a product, headphone.

yearly harvesting compared to the metal, they will be lighter compared to any other primary material for product development (Khan *et al.*, 2018). In that sense, the biobased material has a huge potential in the product development sector.

A product, in this particular case, biobased product is a crude thing which satisfies the customer need and it is also related to the economy. There is a relation between design and manufacturing of a product. If there is no customer there will be no necessity of the product. Before designing and fabrication of a product, first material is required and according to design. After that selection, the material needs to be processed in order to reduce the fabrication complexity, cost, and improve sustainability, durability, reliability, and customer satisfaction. Moreover, the product design has a great impact on product manufacturing as well as the product life cycle. In macro, micro as well as nano biobased product development sector, the fabrication method is dependent on the design. In addition, the design of a biobased product is dependent on the performance of the product (Basha *et al.*, 2015). Thus, design and manufacturing are interdependent.

The design and manufacturing of biobased products are important issues to attain the best performance from the primary biobased material. Moreover, there are different types of challenges for successful biobased product development. In present article, an emphasis is given on these two topics for successful product development. One is key design and other is manufacturing challenge regarding biobased product development. Furthermore, there has been no such comprehensive survey on the challenges of biobased product development and design issue. And authors intend to fill this gap in present article. The approach presented in this study will make a significant contribution to develop a biobased product design and successful manufacturing. Section "Introduction" outlines the key design factor for successful product development. Under this section, the challenges of designing biobased product are also highlighted. Section "Key Design Factors for Biobased Product Development" defines the manufacturing challenges regarding biobased product development. Furthermore, Section "Manufacturing Challenges for Biobased Product Development" and Section "Limitation of Biobased Products" deal with the problem and related solution regarding biobased product designing as well as manufacturing. Finally, concluding remarks are delivered in Section "Conclusion".

Key Design Factors for Biobased Product Development

This section describes the key design factors for biobased product development. Design should be appropriate to fulfill a successful product service. Furthermore, achieving the desired product dimensions is a complicated task. For reducing the number of trials and errors, a finite element method is highly useful (Soury *et al.*, 2009). There is a tendency that the final structure is overdesigned (Awad *et al.*, 2012). Thus, it is important to design a product properly for successful development. Furthermore, synthetic fibers are easy to manufacture with accurate criteria, whereas biobased fiber criteria are uncertain. Synthetic fibers are the competitors of the natural fiber thus, appropriate design of the biobased product is important to sustain in this artificial world. The design is qualitative as well as quantitative. The final cost of the product, aesthetic view and risk tradeoff in the product development mainly depends on the design of the product. To obtain the desired output, biobased material particularly, fibers are chemically treated which leads to better bonding between biobased material and other reinforcing material, as well as additional treatments, increase the acetylation, biobased material's surface heterogeneity, p^H level, orientation in case of fiber (Khan *et al.*, 2018). If the design is appropriate, there will be a negligible amount of problem during the product fabrication, assembling, quality control, and operational performance. During design of a product, the following items need to be considered on the subject of successful biobased product development.

- (1) Appropriate material selection
- (2) Shape of the product (Aesthetic) optimization
- (3) Fabrication and assembling fixation
- (4) Tolerance of product consideration
- (5) Environmental sustainability consideration

Despite the broad scope, in this article, the discussions will be limited to the topics in the above five categories. Different scholars provide an excellent review of the engineering design literature, while a number of survey papers have been published

Fig. 3 Uncertainty of natural material regarding (a) tensile strength- E-modulus, (b) CO₂ emission- density and (c) Data storage system. Reproduced from (a) Ullah, A.M.M., Shahinur, S., Haniu, H., 2017. On the mechanical properties and uncertainties of jute yarns. *Materials* 10 (5), p. 450.

reviewing the metallic product (Krishnan and Ulrich, 2001) and biobased product. Important design factors are going into detail in the following subsection.

Appropriate Material Selection

Typically, most of the production cost is occurred due to the processing of material (Banerjee, 2014). Moreover, cost due to transportation and fabrication process is dependent on the material selection for a product. In addition, other parameters (such as sustainability, durability, quality along with reliability) for a component of the product also depend on the material selection. A similar story is true for biobased products. Before designing a biobased product or a component selecting an appropriate biobased material is required for durable, reliable, efficient, and sustainable biobased product development. However, in the case of biobased product, there is uncertainty in the criteria (C) of biobased material (A) (Shahinur and Ullah, 2017) which can be represented by Fig. 3(a).

From Fig. 3(a) and (b), it is clear that there is a variation in mechanical properties as well as sustainable properties in case of metallic as well as the natural material. Other materials have similar types of uncertainty in their criteria. However, these types of uncertainties are more prominent in the case of biobased material as they grow naturally. Thus, based on the different proposed data base of biobased materials (see Fig. 3(c)), a designer cannot select the design parameters for further biobased product development. Therefore, based on this database material selection is critical. To develop a biobased product, it needs technical information or data of related materials criteria that are logically arranged and organized through following a reliable method. There are different types of databases available regarding the major families of materials such as metals, ceramics, polymers, and composites (Ashby, 2007; Granta Design, 2017), however, it is disorganized in case of primary biobased material particularly natural fiber or any other form of natural material such as yarn, fabrics, and nanoparticle. Different authors suggest different types of natural fiber databases where data are represented as CRISP (Fig. 3(c)①), Group of crisp (Fig. 3(c)②), range (Fig. 3(c)③), group of range (Fig. 3(c)④), distribution, and possibility distribution (Biswas *et al.*, 2013; Ganguli, 2013; Bongarde and Shinde, 2014; Hossain *et al.*, 2014; Pickering *et al.*, 2016; Ullah *et al.*, 2017). When data of a criterion for a bio-material is represented as a range (see Fig. 3(c)③ and Fig. 3(c)④), has wide variation from one researcher to another and unclear the method for data representation, is unreliable for designing a biobased product. Researchers also suggest the database depending on the condition (in case of fiber, gauge length is one of the conditions for testing a specimen) as well as the assumption consideration (normal distribution, Weibull distribution as shown in Fig. 3(c)⑤). Both of these databases have variation from one researcher to another for a single criterion of a biobased material and they are unreliable to select the design a parameter of the biobased product. Based on the above contemplation, data needs to be quantified and stored as database using a single transparent method like possibility distribution as shown in Fig. 3(c)⑥ (see Shahinur and Ullah, 2017 and Sharif Ullah and Shamsuzzaman, 2013 for detail). This can be an open research topic. After quantification of the data for a particular criterion, selection of a material for a product is needed. In addition, there are many methods (such as Technique for Order of Preference by Similarity to Ideal Solution (TOPIS), Fuzzy simulation, Analytic Hierarchy Process (AHP), Ashby method, VIKOR, Preference Ranking Organization Method for Enrichment of Evaluations (PROMETHEE), ELimination and Choice Expressing Reality (ELECTRE), Genetic algorithm (AL-Oqla and Salit, 2017; Gul *et al.*, 2017; Babanli *et al.*, 2018) available to select material for a component of a product. Under uncertainty, the method of material selection would be different. Thus, material selection method development for biobased product where biobased material is in the form of fiber or any other (for example, particle, chopped, long) is an open research topic.

Besides, the data of a criterion for a natural material are big as well as uncertain due to variation in the experimental methods (Ashby, 2007), surrounding conditions and non-homogeneity in their material structure. Thus, the dealing of these types of data is different from as usual man made material data. Therefore, this is another research area for developing the method to deal with

Fig. 4 Data flow from generator to end user.

such big data. As a result, the data should be analyzed efficiently. Furthermore, natural fibers data are heterogeneous. For this reason, a storage system (as shown in [Fig. 4](#)) needs to be developed for further use of the data.

This is another new research topic for biobased-product development. From the developed data base engineer, designer, as well as the manufacturer will be systematically benefited as shown in [Fig. 4](#). After the generation of the database, the designer will use this data for product development, particularly physical shape considering manufacturing method, assembling of the components, environmental issue, finishing, and tolerance of the product.

Shapes of Product Optimization

Optimization of physical design for manufacturability is essential, to ensure the success of manufacturing for a biobased product ([Lin et al., 2007](#)). However, the biobased material are moderately comparable to other materials, the shape of biobased products need to be adopted compared to the traditional product. Performance has been enhanced using variation in the shape of the product. For example, weaving design of fabric makes them bulletproof ([Milne, 2014](#)). In addition, low strength paper material is used in the construction material by changing the shape of the primary as well as secondary material. Furthermore, the shape of a constituent part in the final product also has an influence on its performance. For example, a plain paper is easily torn whereas diamond shape inside the paperboard makes them high strength construction material. Biobased material is also used in the construction material in Japan floor top (see [Ban, 2000](#) for detail). Furthermore, biobased material dimensional stability is poor compared to metal. Whereas biobased material has multi-directional properties due to non-homogeneity in its structure. In order to develop a biobased product, the shape should be modified to take advantage of its directional properties, which will have a positive impact on the cost, weight, and performance. For example, a rooftop can be designed honey-comb shape when biobased material is used for product development because this design enhances the performance of the roof ([Ban, 2000](#)).

Various types of modified window panel designs are now available for houses and offices. Due to this modified design of the window panel, the strength, efficiency, and durability are increased however, the weight and fuel cost are decreased. In addition, a moderate design of a table ([Sciarra et al., 2010](#)) made of biobased-material is now also available. For better service, the shape of the products needs modification. For example, in the medical sector, the patient beds now have six different types of movement whereas only four types of movement were available in the early version of the design ([Portillo-Velez et al., 2016](#)). Such types of upgrading of specific shape or design of the product are important for better service in daily life activities. Sometimes the shape is changed due to the fabrication process of the product. Last but not least, the physical, mechanical and other properties of the biobased materials are not like metallic material. Due to this, when biobased material will be selected for construction material, shape of the product should be selected properly which make them easy to fabricate and assemble.

Fabrication and Assembling Fixation

After the creation of a database (through the research) for a criterion of a biobased material, designer selects a biobased material for a components, and finally fabricats (using an appropriate manufacturing method) and assembles the components for the end product. Thus, one of the important design factors of the biobased product is the fabrication method, which has an effect on the performance of the product. The shape of the product cannot be optimized through a single manufacturing method. In the case of biobased composite fabrication, drying, electro-spinning, gelling, precipitation, hot press, injection molding, and hand layup methods are available. For example, Col-nHA (Collagen Hydroxyapatite) composite can be fabricated through drying, electro-spinning, gelling, precipitation, and hot pressing. However, manufacturing method had the effect on the performance (such as mechanical, physical as well as chemical) of the biobased product in macro, micro as well as nano levels (see [Basha et al., 2015](#) for detail). Thus, it is important to select an appropriate method during the design of a biobased product. One of the biobased materials is biobased fiber which can be used as a raw or composite form in the biobased product. In the case of a composite, biobased materials need to be modified by chemical, mechanical as well as physical treatment. Mixing is also not uniform all around the composite during the composite fabrication. To increase the material surface area of the product the raw biobased material is converted into micro or nano dimensional form. Different types of researches regarding the biobased based nano product are being carried out and better performance was realized from the products in medical ([Basha et al., 2015](#)), and aerospace industries ([Khan et al., 2018](#)).

Table 1 Transformation of polypropylene (PP) matrix and biobased material

Material	Modified	Material	Modified
Virgin	Virgin Polypropylene	Jute Fiber	Composite
Grafted	MAgPP (Shahinur <i>et al.</i> , 2017a,b)	Grafted jute fiber	Grafted fiber composite
Electrical coating	Electrical conductive PP (Kalaizidou <i>et al.</i> , 2008)	Coated jute fiber (Shahinur <i>et al.</i> , 2017a,b)	Electrically coated fiber composite (Anwer <i>et al.</i> , 2018)
Chemically treated	Flame retardant PP (Alibaba.com, 2018)	Treated jute fiber (Shahinur <i>et al.</i> , 2013)	Chemically treated fiber composite (Suppakarn and Jarukumjorn, 2009)

In addition, to obtain desired criteria of biobased material they are blended or mixed with other man-made or natural biobased materials. In this regards hybrid fiber composites take place to tailor for better performance. Correspondingly, to tailor the performance of the composite the matrix material also comes in hybrid form. Sometimes they are chemically treated or radiated using a different method as shown in Table 1.

In addition, at the start of the design, it must be determined which fabrication method, as well as the assembling method, will be used otherwise the performance of the product will be affected. Besides, different adhesive performs differently during the composite assembling. Regarding this issue, the performance is changed due to assembling and machining of the composite material. Last but not least, 3D-printer using CAD (Computer Aided Design) is also used for prototype development regarding the issue of high accuracy and cheap price for large scale production.

Tolerance of Biobased Product Consideration

Tolerance of biobased product is related to the design, manufacturing method and raw material selection. Tolerance of a biobased product is also dependent on the product consumption condition. When the biobased product is used in critical applications (for example, space, civil, aircraft, medical) the tolerance of product development becomes important. As biobased materials are easily degraded in contact with moisture and soil, their performance will change (Katogi and Takemura, 2015). Therefore, the biobased product life time is limited under certain weather condition and after that time limit they are recycled or disposed. However, in the case of controlled weathering condition, their performance can be improved (Shahinur *et al.*, 2017a,b). In the medical sector, the biobased products are categorized into micro, macro, as well as nano dimensions. Moreover, the immune system of the living body in changing day by day, thus, the adoption of biobased composite for particular diseases is changing. Thus, modification of biobased composite (Basha *et al.*, 2015) is needed with the update of diseases. Thus, the tolerance level of the product is important which can be developed during the design time. To increase the tolerance level of the biobased product in different sectors, different scientists are working on biobased composites. Based on the above contemplation it can be concluded that tolerance level of a biobased product can be improved if it is considered during the design.

Environmental Sustainability Consideration

During product design, the environmental impact of the product needs to be considered along with the customer aspiration. A product itself has an environmental effect whereas product development or manufacturing process has a wide range of effect on the environment as shown in Fig. 5.

From Fig. 5 it is clearly observed that in the case of ecological pollution, the factory emits different types of hazardous gases during the product life cycle from biobased material to end product (Office, 2018). If the number of exposure is reduced, the CO₂ footprint of a product will be less. The biobased material, particularly plants fiber, CO₂ absorption, and O₂ emission (enrich the environment) during fiber production are higher whereas they emit less CO₂ during primary material production as they are lightweight and less dense compared to metallic and other materials. Thus, research is needed to reduce the CO₂ emission during secondary material production for a sustainable product development. Furthermore, during the processing of the primary material they emit different types of health hazardous gases including CO₂, CFC, formic acid, formaldehyde, benzene, and different types of toxic material (for example, Mercury, Lead, Cadmium, Tin, and Arsenic) are released into the environment (Aikpokpodion *et al.*, 2013). Thus, it is important to design product based on customer need, which meets environmental sustainability as much as possible.

Weight and transportation cost are related to each other, so it is required to design lightweight product in order to reduce fuel consumption which has a great impact on the environment. Processing cost of a product needs to be optimized to make the product cheaper and keep the environment healthy. As biobased fiber and material have hydroxyl (-OH) group and they absorb moisture from the environment as well as their moisture regain varies to a large extent, which will affect the dimensional stability of the product. Hence, for sustainable product development, one needs to select an appropriate biobased material and fabrication method which do not emit lots of CO₂ in the environment.

Fig. 5 Effect of biobased product development in the environment.

Manufacturing Challenges for Biobased Product Development

During the manufacturing of a product, the producer faces numerous types of challenges, which will be briefly discussed in this section. Different types of biobased macro, micro, nano or above nano scale) composites (for example, collagen, gelatin, and chitosan biobased composite) have shown different mechanical and physical properties due to the variation of the manufacturing process (Basha *et al.*, 2015). As a result, their performance is hampered in a specific area. Thus, manufacturing method optimization is important. However, during the design, it is optimized while the product performs differently in the application field. As a result, the manufacturing method is modified to obtain the desired performance. During the manufacturing of a product, there are few disadvantages of using experimental investigation such as high cost and longer time consumption. This types of challenges need to be managed for better product development. In addition, product manufacturing cost has an important effect on the developing countries where resources are limited. That means, when resources are limited design development is an important issue. In addition, there is some limitation of nano product development due to technology deficiency. Additionally, the manufacturers use a method which is easy, less time-consuming as well as cheap to supply the product in time. To attain these types of quality of the fabrication method they face some types of challenges which are listed below. Besides, in this section attention is devoted to the manufacturing challenges based on very limited literature available regarding this field.

Manufacture handling and safety, skilled labor shortage, Internet of things (IoT), manufacturing the right inventory level, robotics and automation change, system usability, customer self-service application, intelligence from a machine, project management, wastage management (Boggess, 1994), environmental consideration, lack of supply chain transparency, product inconsistency are considered as some of the important challenges for sustainable biobased product development. Furthermore, for biobased product manufacturing by 3-D printing with high accuracy is a big challenge. To obtain better performance using 3-D printer design needs to be improved.

Huge data is one of the major challenges for manufacturing as well as design while the biobased-materials data are uncertain. Secondly, the supply chain issue is another important factor for biobased product development as the production of a particular region is fully dependent on climate, disaster, and farmers' wish. Furthermore, biobased material, particularly plant production is changed from year to year. Business downtime is another factor of the manufacturing challenges of the biobased product because new materials having improved properties are being developed day by day which is the competitor of the biobased-material. On the other hand, unplanned maintenance, development, and innovation of the new technology, health care cost, are also the challenges in the biobased product development (Anon, 2017). In a factory or farm, the working condition should be fair and protect human rights. As biobased material have OH, low mechanical, thermal, physical performance, manufacturer faces following types of challenges during industrial production.

Moisture Absorption

In the case of biobased product, moisture is one of the important issues for industrial manufacturing. As biobased-material particularly natural fibers are hydrophobic and they have free hydroxyl ($-OH$) group, they absorb moisture and the dimensional stability hamper by Eq. (1). Thus, water retardant treatment required for long term sustainable biobased-product development. Fuqua and Ulven (2012) has shown improved water retardant quality in the biobased product due to the addition of compatibilizers in the composite. Therefore, these types of pre or post treatment may improve product quality as well as reliability.

During manufacturing, different types of product such as raincoat, umbrella they are using a coating to retain the dimensional stability from moisture, dew, fog, as well as rainwater. Furthermore, by improving this property bamboo fiber is used in sanitary and baby napkin regarding the environmental sustainability issue (Dutta, 2017).

Bio-based products have wide variety of applications including textiles and home furnishings. Biobased materials get shrunk after treatment (sizing, de-sizing, scouring, and bleaching) during dyeing method, and become faded due to sunlight which requires improvement through use of chemicals (during industrial production), which are not bio-degradable. Different categories of researches are going on dyeing and printing of biobased product using bio-material. Bio-based dyes (such as lichi leaves, indigo, merigold onion peel) and printing materials have some limitations (such as expensive, limited shade of color is achievable, unsustainable). That is why, they need to be improved for sustainable printing and dyeing industries. Vankar *et al.* (2008) and Miah *et al.* (2016) have been working on bio-based dyeing from biobased material which would be eco-friendly.

Moderate Mechanical Properties

Biobased materials are environmentally sustainable. The alertness of the biobased product is growing due to the adverse side effect of the artificial material. Mechanical performance is poor in case of biobased-material compared to the metallic material. Different researchers have obtained a wide range of mechanical properties using different modifications (for example, chemical, physical, and mechanical) in the biobased material. Furthermore, biobased-material is incorporated in the polymer and their properties are enhanced in the final product (Shahinur *et al.*, 2017a,b; Dos Santos *et al.*, 2018). Depending on the application, biobased material is incorporated in different types of matrix material for biobased composite manufacturing. Thus, these types of modification of the biobased material are important for quality biobased product development. Furthermore, biobased fabric shrinks due to detergent wash, which needs to be improved. Thus, it is an open research topic.

Thermal Performance

In mass production, thermal performance is an important issue for cutting or, machining. Due to cellulose content natural fibers become highly flammable which can be improved by chemical treatment (Khan *et al.*, 2018). Due to cellulose, hemicellulose, and lignin, natural materials start to burn at 200–800°C (Shahinur and Hasan, 2019) whereas some metallic materials melt at above 2000°C. Thus, thermal tolerance needs to be improved for machining of the biobased product. Thermal performance can be improved through different modifications in spray, and solid phase of biobased product (Soury *et al.*, 2009; Shahinur *et al.*, 2013). Phosphorus salt is used in solid phase for improvement of thermal properties whereas halogens with phosphorus act in the vapor phase (Ulsamer *et al.*, 1980). Due to the modifications, biobased-materials become less biodegradable whereas their performance is enhanced. Thermal degradation also affects mechanical performance. Due to heat, the structure of bio based material is changed and mechanical properties are hampered. For example, Shahinur *et al.* (2013) have revealed that when thermal properties are increased, mechanical properties are decreased due to fire retardant treatment on the biobased material. However, Huang *et al.* (2003) found an improvement of mechanical properties with thermal properties due to chemical modification.

Poor Bonding Mechanism

Poor interfacial strength of the biobased composite is another challenge for manufacturing. Due to surface roughness and hydrophobicity, the poor bonding occurs in the biobased composite particularly, fiber and the matrix. Furthermore, the biobased-materials are chemically treated which are toxic or not environmentally friendly. Though in the developing country the biobased product development will generate employment opportunities, the percentage of chemical incorporation is small, which needs to be overcome through modern technology to ensure environmental safety.

Non-Homogeneity

When biobased products are manufactured the quality standard of the products is not consistent due to the non-homogeneous material characteristics. In addition, due to this criterion the mechanical, thermal, structural, physical as well as the aesthetic performances of the biobased material may vary significantly. As they grow naturally there is non-homogeneity in the structure of a biobased material. The percentages of bio-elements are not homogeneous all over a particular bio-material. For example, biobased fibrous plants' lignin content varies from one portion to another. Moreover, in case of biobased fiber the percentages of bio elements vary with the age of fiber. Furthermore, biobased composite is produced to control this non-homogeneity. In the case of biobased composite one material is mixed with other material or biobased material. By changing the genome sequence of a biobased material, this non-homogeneity might be improved. Thus, it is a new area of research for further improvement in biobased material non-homogeneity.

Limitation of Biobased Products

Though biobased products are attractive due to their low weight, cost, CO₂ emission, and O₂ absorption, they also have some limitations. Among the limitations, biobased products face a critical problem of performance degradation when they expose to an outdoor environment which needs to be minimized. In addition, the limitations of biobased materials cause machining, milling, and drilling problem during the manufacturing of a biobased component and need to overcome for a sustainable biobased product development. Abrate and Walton (1992) and Mohamed *et al.* (2016), informed the machining technique of product which could be suitable for biobased product. Thus, this sector needs to be improved for biobased product machining. Despite having the machining issues, the researchers are giving more importance to the opportunity of environmental sustainability with the biobased products.

Conclusion

During the design of a biobased-product considerations should be made on the uncertainty in biobased material properties, shape optimization in micro, macro as well as nano field, manufacturing and assembling fixation, and finally tolerance of the biobased-based product. Thereafter, designing a product when it goes for manufacturing faces different problem which needs to be solved for sustainable development. Biobased products are being developed in huge varieties due to customer need, which need enabler during the product design and manufacturing for mass customization (AlGeddawy and ElMaraghy, 2011). In addition, in case of product design economic growth of a country, national and individual prosperity are the controlling factors. Furthermore, biobased-materials have a wide range of performance parameters from the highest and lowest. Thus, one needs to balance them in term of customer need and satisfaction compared to the other existing products. If value added product is developed through appropriate design, with other supporting factor and step of the marketing, biobased products will be sustainable in the market. There are different areas for further developments in the product design and the challenges to overcome regarding the manufacturing of biobased products. As a result, farmers, suppliers, and users will be benefited and the earth will stay green for a longer time for the next generation.

The Effect of CaCO_3 Nanoparticles and Chitosan on the Properties of PLA Based Biomaterials for Biomedical Applications

Md S Islam and Md M Islam, Bangladesh Army University of Engineering and Technology, Qadirabad, Bangladesh
Kh N Islam, Chittagong Veterinary and Animal Science University, Chittagong, Bangladesh

© 2020 Elsevier Inc. All rights reserved.

Introduction

Blending of chitosan (CS) with suitable polymer matrix is an often used and effective method to improve the physical and mechanical properties of blend composites. Polylactic acid (PLA), chitosan (CS) and nanoparticles based biocomposites/biomaterials as natural polymers have proven its high potential in biomedical applications, such as tissue engineering, wound dressing, drug delivery system, orthopedic devices, surgical sutures, enzyme immobilization, catalysis, antibacterial coatings and so on. These biocomposites are non-toxic, antibacterial, biodegradable and biocompatible biopolymers (Zhang and Cui, 2012; Jayakumar *et al.*, 2010).

Poly(lactic acid) (PLA) is bioactive and biodegradable thermoplastic aliphatic polyester derived from various renewable resources, such as corn starch, sugarcane, tapioca roots and so on. Generally, PLA is produced from lactic acid and the cyclic diester, lactide monomer. The most frequently used procedure of PLA production is the ring-opening polymerization of lactide with different metal catalysts in solution, in the melt or as a suspension. The metal-catalyzed reaction overlook to cause racemization of the PLA, decreasing its stereo regularity compared to the starting material (Grande and Carvalho, 2011).

There have various different types of polylactic acid to include Regular PLLA (Poly-L-Lactic Acid), Racemic PLLA (Poly-D,L-Lactic Acid), PDLA (Poly-D-Lactic Acid) and PDLLA (Poly-DL-Lactic Acid). Each of them have slightly different individual characteristics but are similar in that both of them are produced from a renewable resource (like lactic acid: $\text{C}_3\text{H}_6\text{O}_3$). The production procedure of PLA is very cost efficient. When exposed to the environment PLA degrades naturally which makes its versatile applications. There has a high potential for PLA to use in short lifespan applications where biodegradation is highly required. PLA has a crystallinity of around 37%, melting temperature 173–178°C, glass transition temperature 60–65°C and the tensile modulus 2.7–16 GPa (Södergård and Stolt, 2002; Middleton and Tipton, 2000). PLA is generally soluble in chlorinated solvents, hot benzene, tetrahydrofuran and dioxane (Garlotta, 2001). The biodegradation of PDLA is milder than for PLA due to having higher crystallinity of PDLA. PLA is fairly unsuitable for high temperature applications due to its relatively low glass transition temperature (generally 44°C to 63°C) and it is slightly more brittle than ABS for 3D prototyping.

The applications of natural polymers which are biodegradable and biocompatible has become increasingly important nowadays because of their outstanding properties, such as natural abundance, low costs, non-toxic and wide range of applications (Mathew *et al.*, 2005; Jonoobi *et al.*, 2010). Recently biodegradable polymers have been focused for the preparation of food packaging films from the concern about the environment. These types of food packaging films are usually highly loaded with antimicrobial agents to inhibit growth of food-born microorganism when come contact with foodstuffs (Jayakumar *et al.*, 2010). PLA has many other applications such as barriers for sanitary products, diapers, milk and water bottles and also used in retail markets for fruits, salads and vegetables (Pei *et al.*, 2010). PLA is being used because it functions very well and provides excellent properties at a competitive price.

Chitosan (CS) (poly-1,4-D-glucosamine) is a biodegradable natural polymer obtained from renewable sources such as from the shell of shellfish and the wastes of the seafood industry. It may also be produced by alkaline deacetylation of chitin. It has some novel properties including biodegradability, biocompatibility, antibacterial, natural abundance, wound-healing activity and so on. Chitosan biopolymer has a wide range of commercial and possible biomedical applications including wound dressing, tissue engineering scaffolds, drug delivery system, bandages to reduce bleeding and other hemostatic agents, as an antibacterial agent and so on. Hemostatic properties of chitosan help to reduce pain by blocking nerve endings (Kumar *et al.*, 2014). Chitosan is frequently used in the field of bandages because of its antioxidising, antiseptic, antiviral, antibacterial and hypoallergenic properties. Chitosan-based plastic wrap doubles the shelf life of some foods. It is frequently used in food processing industries as edible coatings or films to extend foodstuff's shelf life, such as fruits, meat, fish and seafood because of its non-toxic and edible properties. CS is reported to be an active polymer with antimicrobial and antifungal activities because of its biodegradability and biocompatibility. Among the biodegradable polymers, it is one of the most abundant in nature. Moreover, with the increasing attention about the environment, the newly developed biodegradable packaging materials, such as CS films, could be an interesting alternative to petroleum-based synthetic polymers. In order to fulfill the aforementioned applications, various investigations and researches have been devoted to produce new polymer systems incorporating Chitosan as a bioactive material.

PLA has few drawbacks that limit its use such as poor thermal stability, low water vapor and gas barrier properties and embrittlement (Petersson *et al.*, 2007; Qu *et al.*, 2010). These negative properties of PLA may be overcome by blending it with suitable synthetic or natural polymers. Blending is a more effective and easier way to attain desired properties of multiphase polymeric materials (Sanadi *et al.*, 1994).

Therefore, PLA may be an effective and suitable option to blend with chitosan. However, the problem is that PLA is not miscible with chitosan due to their differences in polarities. Therefore, it is essential to mix up a third polymer in order to reduce

Table 1 The properties of PLA and chitosan

	PLA	Chitosan
Chemical and physical properties	Thermoplastic Nucleating agent Crystallinity of around 37% Glass transition temperature 60–65°C Aliphatic polyester Tensile modulus 2.7–16 GPa	Complexing and chelating properties Soluble in dilute aqueous acidic solutions High viscosity Ionic conductivity High crystallinity and hydrophilicity Strong nucleophile
Biological properties	Biodegradable Bioactive Renewable resource Antibacterial Biocompatible Biopolymers	Adsorbable Biocompatible Bioactive Nontoxic Bioadhesive Antimicrobial Hypolipidemic

the interfacial tension among the polymers to improve the attractive forces between the discrete phases in order to attain the compatible blend. **Table 1** shows various properties whereas **Table 2** shows different important applications of PLA and chitosan.

Calcium carbonate is a chemical compound with the formula CaCO₃ is an important incorporating agent with the PLA/CS blend biocomposite. It is a common substance found in rocks limestone and minerals calcite. It is generally found in pearls and the shells of marine organisms, snails and eggs. Calcium carbonate has medicinal applications as a calcium supplement or as an antacid. Stimulated body fluid with excellent apatite-forming ability of ceramic-polymer biomaterial was prepared by hot pressing a mixture of poly-L-lactic acid (PLLA) and calcium carbonate. The modulus of elasticity of the biocomposite was effectively improved by 3.5–6 GPa, when 30 wt% calcium carbonate was introduced. The composite showed no brittle fracture behavior and a comparably high bending strength of approximately 50 MPa (Kasuga *et al.*, 2003).

By melt extrusion process, precipitated calcium carbonate (PCC) and halloysite natural nanotubes (HNT) of PLA nanocomposites were prepared. Xuetao Shi described the thermal, mechanical, crystallization and morphological properties of HNT/PLA, HNT/PCC/PLA and PCC/PLA composites (Shi *et al.*, 2015). Young's modulus is increased, but tensile strength is decreased with the addition of inorganic nanofillers in PLA composites. The elongation at break properties is increased with the incorporation precipitated calcium carbonate (PCC) (Shi *et al.*, 2015).

Various commercial PLA products are already available in the market. These include long life consumer goods such as compact disc (CD), computer keys, casing of walkman, blanket, and different packaging products such as envelope with transparent window, transparent paper bag for bread, trays, and bowls for fast food and some agriculture and horticulture products.

Modifications of PLA

As discussed early, PLA has poor chemical modifiability, mechanical ductility and poor hydrophilicity. Therefore, chemical and physical modifications such as incorporation of functional monomers with different compositions are very much helpful to improve its applicability.

Chemical modification of PLA

Cross-linking and copolymerization are two major techniques for chemical modification of PLA.

Cross-linking

Cross-linked PLA can be obtained by various chemical reactions or by irradiation. Quynh attained stereocomplexes by cross-linking blends of PLLA and low molecular weight PDLA (Quynh *et al.*, 2009). By radiation cross-linking, alkaline hydrolysis and enzymatic degradation can be controlled. Without irradiation, only by chemical reactions between linking agents and the polymer chain with various gel fractions and cross-linking densities, PLA can be modified (Agrawal *et al.*, 2010).

Table 3 Mechanical properties of pure PLA and its composites (mean values; all the specimens were tested at 0°C)

Types of samples	Young's modulus, (N/mm ²)	Tensile strength, (N/mm ²)	Charpy impact strength, (KJ/mm ²)	Elongation at break, (%)
Pure PLA	3820.2	30.1	24.4	0.83
Hemp-PLA	8064.2	57.5	9.5	1.24
Cotton-PLA	4242.3	41.2	28.7	3.07
Kenaf-PLA	7138.6	52.9	9.0	1.05
Hemp/Kenaf-PLA	7763.8	61.0	11.8	1.22
Hemp/Lyocell-PLA	7034.9	71.5	24.7	1.65
Lyocell-PLA	6783.8	81.8	39.7	4.09

Copolymerization

Polycondensation of PLA with lactone-type monomers generally obtain low molecular weight copolymers. This type of polycondensation is possible for the hydroxyl group and carboxyl groups of lactic acid. The crystallinity of this type of copolymers is increased. Biocompatibility, hydrophilicity and antibacterial activity are increased by obtaining copolymerized products of PLA with poly(ethylene glycol)(PEG) and poly(ethylene oxide)(PEO) (Metters *et al.*, 2000).

Physical modifications of PLA

PLA can be modified to increase various applicable properties by different physical methods such as plasticization, composition variations and blending method.

Plasticization

Normally, PLA has poor elongation properties as glassy polymer. The ductility and softness of PLA can be increased and the glass transition temperature, T_g can be lowered by modifying the PLA with various biodegradable plasticizers with low molecular weight and high boiling point. Ljungberg have blended PLA with five various plasticizers (triethyl citrate, tributyl citrate, acetyl tributyl citrate, acetyl triethyl citrate and tri acetone) and observed that tributyl citrate and triacetone were more effective as plasticizers which decrease T_g of PLA (Ljungberg and Wesslén, 2002).

Composition variations

Graupner *et al.* (2009) made composites from various types of natural fibers (such as hemp, cotton, kenaf, etc.,) and some modified cellulosic fibers by compression molding. A few types of surface modifiers can enhance adhesion between the fibers and the PLA matrix. Wang made a composite from PLA and microcrystalline cellulose modified by L-lactic acid (Wang *et al.*, 2002). The tensile strength of the composite was higher than pure PLA. The mechanical properties of these fiber composites are summarized in Table 3

Blending

Jamshidian performed extensive reviews in "Food Science and Food Safety" and found that huge investigations have been done on the blending of various polymers with PLA such as poly(ethylene glycol), poly(vinyl acetate), poly(ethylene oxide), cellulose acetate and poly(hexa-methylene succinate) (Jamshidian *et al.*, 2010). Polymer blending is very effective technique to develop new properties. Various expected properties can be attained by blending with PLA. Xu *et al.* (2009) have blended PLA with a new degradable thermoplastic derived from konjac glucomannan (TKGM) in order to promote the mechanical and processing properties of PLA without sacrificing its biodegradable and biocompatible properties (Table 4).

Materials and Method

Preparation of Nano-Sized CaCO₃ and Characterization

The micron-sized eggshell powders were first prepared according to the method of previous study on almost similar reports which was using cockle shell (Islam *et al.*, 2011). First of all, approximate 250 g of eggshells were scrubbed to remove dirt and washed with distilled water. It is then being boiled for 10 min and cooled at room temperature. The eggshells then washed again with acetone and leave for a day so that it will dry completely and ready for grinding. The outer and inner membranes under eggshells were removed and only the shells were grinded manually using mortar and pestle. The powders obtained were sieved with aperture size of 90 µm to obtain micron sized less than 90 µm in diameter powders. The powders were ready to make into nano-sized calcium carbonate.

For the synthesis of calcium carbonate nano-sized particles, 10 g of prepared micron-sized eggshells were used. 100 mL distilled water was added to form slurry. The mixture was then stirred vigorously for 120 min at room temperature using a magnetic bar and a mechanical hot plate stirrer at the rate of 1000 rpm. The samples were then separated using a filter paper. The product was then dried at 70°C for a day and packed in polyethylene plastic bag for further use. The brownish white sample obtained was then

Table 4 PLA modifications for various applications

<i>Types of modification</i>	<i>Treatments/Materials added</i>	<i>Observed effects</i>
Physical modifications	Annealing	Toughness is increased
	Aging	Glass transition temperature is increased
	Orientation	Tensile and impact properties are improved
	Drawing	Tensile and fracture properties are improved
Copolymerization of PLA	Polyvinyl chloride	Toughness and strength are improved
	ϵ -Caprolactone	Decomposition temperature and crystallinity are increased
	Acrylonitrile-butadiene-styrene	Elongation at break with a slight loss in modulus and impact strength and tensile strength are increased
	D,L-mandelic acid	Mechanical properties and glass transition temperature, T _g are improved
Blending with	Poly ethylene glycol (PEG)	Enhance the crystallinity of PLA and biodegradability
	Poly ethylene oxide (PEO)	Elongation at break is improved.
	Poly ϵ -caprolactone (PCL)	Mechanical properties are highly improved
	Polyvinyl acetate	Percent elongation and tensile strength are increased
	Polycarbonate	Mechanical properties and biodegradation rate are increased.
	Starch with various plasticizers	The price is lowered, crystallinity is increased, T _g and biodegradability are decreased
Modifiers	Poly(1,3-butylene adipate)	Glass transition temperature is decreased but elongation at Break is increased

sent for XRD and FTIR analysis to ensure that pure calcium carbonate was obtained. The powders were then stored to be used to prepare composites.

The structural properties of the formed nano-sized CaCO₃ particles were investigated by the X-ray diffraction (XRD) using Shimadzu 6000 X-Ray machine with nickel filtered Cu K α ($\lambda=1.542$ Å) radiation. The average crystallite size of the CaCO₃ nanoparticles has been calculated from the line broadening using the Scherrer's relation as following:

$$D = \frac{0.9\lambda}{\beta \cos \theta}$$

where D is the crystallite size (in nm), λ the wavelength of X-ray ($\lambda=1.542$ Å),

β the full width at half maximum (FWHM—in radian) intensity and

θ the Bragg diffraction angle (°).

The scanning angle of the XRD analysis was 20–70°C in 2θ at the rate of 10°C min⁻¹.

Fourier transforms infrared spectroscopy (FT-IR) was performed using a Perkin Elmer 1725 X Spectrometer. The CaCO₃ nanoparticles were dispersed and mixed with the KBr particles together and pressed into pellets. The spectrum of CaCO₃ nanoparticles were recorded in the range of 4000–280 cm⁻¹. The transmission electron microscopy (TEM) studies were performed with Hitachi H-7100 TEM. The sample was prepared by dispersing the drop of colloid on the copper grid, covered with the carbon film and the solvent was evaporated. Micrographs were taken to study the morphological and crystallinity of CaCO₃ nanoparticles.

Preparation of Biomaterials and Characterization

Materials

Poly(lactide (Nature WorkTM PLA 300ID) in pellet form having a specific gravity of 1.24 g/cm³ and a melt flow index (MFI) of 15 g/10 min (190°C/2.16 kg) was used for this study. Commercially available chitosan (practical grade 75% DD) from sigma Aldrich was used as the reinforcing filler. Nanoparticles of 2% CaCO₃ nanoparticles was used as a compatibilizer. Chloroform was used as solvent secured from Merck, Malaysia.

Preparation of PLA/CS/CaCO₃ nanoparticle composites

Different weight percentage (wt%) of CaCO₃ nanoparticles (0.5, 1 and 2 wt%) was mixed into chloroform respectively together with 10 wt% PLA pellets and 5 wt% CS. The solution was stirred in a water bath at 60°C until all the pellets were fully dissolved. The PLA/CS/CaCO₃ NPs solution was then casted on Petri dish and left at ambient temperature for 24 h for solvent to evaporate. The thickness of the cast solution was about 100 μ m. The resultant films were then peeled off from the casting surface.

Preparation of PLA/CS composites

10 wt% of PLA pellets was mixed together with 5 wt% of CS in chloroform solution. The solution was stirred in a water bath at 60°C until all the pellets were fully dissolved. The PLA/CS solution was then evenly casted on Petri dish and left at ambient temperature for 24 h for solvent to evaporate. The thickness of the casted solution was about 100 μ m. The resultant film was then peeled off from the casting surface.

Fig. 1 XRD pattern of CaCO₃ nanoparticles prepared at room temperature.

Preparation of pure PLA film

A 10 wt% solution of PLA pellets in chloroform was prepared by stirring the solution in a water bath at 60°C until all the pellets were fully dissolved. The PLA solution was then evenly casted on Petri dish and left at ambient temperature for 24 h for solvent to evaporate. The resultant film was then peeled off from the casting surface. The developed composites were then tested for characterized various properties.

Structural and surface morphology of developed composites were analyzed through Fourier transforms infrared spectroscopy (FT-IR) and scanning electron microscopy (SEM). FTIR was performed using a Perkin Elmer 1600 Infrared spectrometer. The significant transmittance peak at a particular wave numbers was measured by using the “find peak tool” provided by Nicolet OMNIC 5.01 software. SEM analysis was carried out using a SEM-EDX Oxford INCA 400 model at an acceleration voltage 10 kV. The samples were sputter-coated with gold to prevent charging. Mechanical test was carried out using the Instron 4400 Universal Tester to measure the tensile strength at the point of breakage for each sample. Tensile tests were carried out at room temperature, according to the ASTM D882 type V. A fixed crosshead rate of 10 mm/min was utilized in all cases and the results were taken as an average of five tests.

Results and Discussions

Characterization of Nano-Sized CaCO₃

X-ray diffraction (XRD)

Fig. 1 showed XRD pattern of CaCO₃ nanoparticles as prepared from eggshells at room temperature. It was carried out under 20–70°C. The XRD pattern matched to standard aragonite CaCO₃ powder sample (JCPDS file No. 00-041-1475) and also calcite CaCO₃ powder sample (JCPDS file No. 00-047-1743). The XRD curve showed diffraction plane corresponded to 2θ values and tabulated in the [Table 5](#).

These values of diffraction shown a orthorhombic CaCO₃ with lattice parameter of $a = 4.9623 \text{ \AA}$, $b = 7.9680 \text{ \AA}$ and $c = 5.7439 \text{ \AA}$. CaCO₃ nanoparticles was in a mixture of both aragonite and calcite form. Aragonite form 6 diffraction peaks as shown as **Fig. 1** above. $\lambda = 1.542 \text{ \AA}$. The remaining peaks showed value of diffraction matched to calcite form CaCO₃ nanoparticles. Based on Debye Scherrer equation, which relating the width of powder diffraction peak to average dimensions of crystallites in a polycrystalline powder by volume.

$$\beta_s(2\theta)_{hkl} = \frac{K\lambda}{T \cos \theta_{hkl}}$$

Where β_s is the crystallite size contribution to the peak width (FWHM) in radian, K is a constant near unity (0.9), and T is the average thickness of the crystal in a direction normal to the direction to the diffracting plane hkl . The value of K may have slight change depending to the FWHM or integral width chosen to be characterizing the peak breath. It was crucial to understand precisely dimensions that were used on the equation and how the crystallite size broadening was estimated accurately.

As the diffraction peaks shown were sharp, it can be concluded that CaCO₃ nanoparticles were highly crystalline. The diffraction peak with 2θ value of 29.529° having the plane (1 0 4) was used to calculate the crystallite size contribution. It was the prominent peak and found that the size contributed was 8.104 nm.

**Fig. 2** FTIR peaks of CaCO₃ nanoparticles.

Fourier transform infrared spectra (FTIR)

Fig. 2 shows the FTIR spectrum of the synthesized CaCO₃ nanoparticles, which was acquired in the range of 4000–400 cm⁻¹. The most prominent peak of carbonates with 1402.52 cm⁻¹ was appeared as asymmetrical stretching vibration C–O bond. This peak was attributing to alkyl group which was present in the aragonite polymorphs. The characteristic peaks, represent CO₃²⁻ of aragonite, were observed at 869.45 cm⁻¹ and 709.93 cm⁻¹. The CO₃²⁻ peaks observed were in OCO bending mode vibration (Andersen and Brecevic, 1991). The weak peaks beside the prominent peaks appeared to be 1795.06 cm⁻¹ was due to C=O bonding of CO₃²⁻ (Chen *et al.*, 2011).

Transmission electron microscope (TEM) for CaCO₃ nanoparticles

TEM analysis was carried out to determine the morphology, size and crystalline nature of the synthesized eggshells based CaCO₃ nanoparticles. **Fig. 3** shows TEM analysis of the CaCO₃ nanoparticles. The TEM images show spherical and rod-shaped CaCO₃ nanoparticles with the average size of 21.3 nm and 548.7 nm respectively (Hassan *et al.*, 2014). Although, the mixture of CaCO₃ polymorphs were synthesized, the crystal size of both spherical and rod-shaped produced were smaller in size than the previous researches. The mixture of CaCO₃ polymorphs were most probably due to absence of catalyst that was used in previous research (Islam *et al.*, 2013). This was due to the catalyst was not suitable for biological purposes. The agglomeration of CaCO₃ crystal was due to their high specific surface areas and the strong tendency to form aggregates (Lam *et al.*, 2009; Wang *et al.*, 2002).

If the particle sizes were to compare between the results of TEM and XRD which was calculated previously, there was a net difference of 62%. The reason behind the variation may be due to nano-sized particles having high specific surface areas and therefore having strong tendency to form aggregates. As the aggregation nature of nanoparticles precise determination of primary particle size were unavoidable with significant error. These also thus explain the necessity of different analysis approach including TEM (Lam *et al.*, 2009).

Fig. 4 FT-IR results of (a) PLA, (b) PLA/CS and (c) PLA/CS/ CaCO_3 .

Characterization of Biomaterials

Fourier transform infrared spectroscopy (FT-IR)

The interaction between PLA, CS and CaCO_3 was investigated by FT-IR spectroscopy and is shown in **Fig. 4**. The FTIR spectrum of the neat PLA (**Fig. 4(a)**) clearly showed the characteristic absorption band in the region of $3500\text{--}3600\text{ cm}^{-1}$, $2946\text{--}2999\text{ cm}^{-1}$ and 1757 cm^{-1} due to O–H stretching, C–H asymmetric stretching and C=O stretching vibration respectively (Jeevitha and Amamath, 2013). On the contrary, it can be seen from **Fig. 4(b)** that the characteristic absorption band of PLA at 3418 cm^{-1} and 2918 cm^{-1} has shifted towards lower wave numbers with narrowband intensity upon incorporation of CS. Therefore, it can be implied that CS adequately dispersed in the PLA matrix and formed PLA/CS composites.

Fig. 4 represented the FT-IR spectra of PLA/CS/ CaCO_3 composites respectively. It was found that the characteristic absorption band of PLA/CS has shifted towards lower wave numbers when CaCO_3 was added into PLA/CS matrix. This indicated some level of interaction and the formation of PLA/CS/ CaCO_3 composites. All these results pointed towards good dispersion and interaction between PLA, CS and CaCO_3 which significantly changed the morphological properties of the composites.

Scanning electron microscopic (SEM)

SEM micrographs of fractured composite samples shown in **Fig. 5(a)** and **(b)** indicated that the PLA/CS fractured surfaces were covered with uneven fibrils layers and a number of micro-voids throughout the surface. This indicates that the two polymers (PLA and CS) were not properly miscible (Balakrishnan *et al.*, 2012).

Conversely, the tensile test fractured surfaces of PLA/CS/ CaCO_3 samples (**Fig. 5(b)**) showed smooth and homogeneous surface upon incorporation of CaCO_3 in the matrix. It can also be seen that the fibrils and micro-holes significantly reduced after addition of CaCO_3 into the PLA/CS matrix. This result indicates that the PLA, CS and CaCO_3 were well blended in the matrix and the

Fig. 5 Typical SEM of (a) PLA/CS (10% CS) and (b) PLA/CS/ CaCO₃ (10% CS).

Fig. 6 Tensile strength of various composites.

interaction between PLA and CS was strong. Thus this result confirms that CaCO₃ significantly improved the adhesion and interaction between PLA and CS (Zakaria *et al.*, 2013; Julkapli *et al.*, 2011). Therefore, the mechanical strength of PLA/CS/CaCO₃ composites should be higher as compared to the pure PLA/CS.

Tensile strength

The tensile strength of the composites was displayed in Fig. 6. Generally, it can be seen that the tensile strength and tensile modulus of the pure PLA composite decreased upon the incorporation of CS. Both the tensile strength and tensile modulus of the PLA/CS composite showed improvements as CaCO₃ nanoparticles being incorporated into the composites up to 1.0 wt% CaCO₃ nanoparticles loading. This same goes to the elongation at break of the composites which showed steady increment up to 1.0 wt% CaCO₃ nanoparticles loading of PLA/CS/CaCO₃ nanoparticles composite.

The effectiveness of the reinforcement to facilitate effective stress transfer in ultimate tensile strength of the composites was the interface of the matrix and filler. Fig. 6 showed that PLA/CS exhibited weaker tensile strength compared to the pure PLA composite. Both the CS and PLA formed intermolecular hydrogen bonds between the N-H of chitosan and C=O of PLA, leading to the tensile strength of the PLA/CS composite. However, the tensile strength of PLA/CS decreased with further increase in the PLA:CS ratio, which may be due to the formation of intramolecular hydrogen bonds rather than intermolecular hydrogen bond, resulting in phase separation between the two main components (Eichhorn *et al.*, 2010). As CaCO₃ nanoparticles being incorporated into the PLA/CS composite, tensile strength of the composite was improved by 34.2% at 1.0 wt% CaCO₃ nanoparticles loading. However, the tensile strength of the composite declined with the increment of CaCO₃ nanoparticles loading until 2.0 wt%. The tensile strength increased with the increase in CS loading up to 5 wt% and then decreased gradually up to 15 wt%. This implies that 5 wt% is the optimum concentration beyond which agglomeration of CS particles occur causing stress concentration within the matrix which consequently lowers the tensile strength. However, PLA/CS/CaCO₃ exhibited a higher tensile strength than the PLA/CS at all CS loading. This may be due to the incorporation of CaCO₃ into the PLA/CS matrix, which increased the compatibility and adhesion between PLA, CS and CaCO₃, thereby resulting in higher tensile strength for composites (Yew *et al.*, 2005).

TGA of nanocomposites

Based on Fig. 7, it was observed that thermal stability of PLA/CS decreased when CaCO₃ nanoparticles was added. This indicated that thermal stability decreased with addition of CaCO₃ nanoparticles. Thermal decomposition of all five composites showed almost same

Fig. 7 TGA thermo grams of various composites.

curve. Pure PLA film showed a better thermal stability than PLA/CS composite which suffered greatest loss by 89.7% as seen from [Fig. 7](#). Thermal stability seems improved as CaCO₃ nanoparticles were incorporated into the composites to offset the effect of addition CS. On the other hand, thermal stability of blended CaCO₃ nanocomposites showed that 1.0 wt% CaCO₃ nanoparticles had highest thermal stability with similar wt% loss with 0.5 wt% CaCO₃ nanoparticles. PLA/CS/2.0 wt% CaCO₃ had same thermal decomposition temperature but had greater loss than that of other blended CaCO₃ nanocomposite.

Antibacterial Activity of Chitosan-Based Materials

Dongwei carried out a research work on synthesis of chitosan-based silver nanoparticles and their antibacterial activity ([Wei et al., 2009](#)). In his work, Chitosan-based silver nanoparticles were synthesized by reducing silver nitrate salts with nontoxic and biodegradable chitosan. The silver nanoparticles thus obtained showed highly potent antibacterial activity toward both Gram-positive and Gram-negative bacteria, comparable with the highly active precursor silver salts. Compared with pure chitosan films, chitosan films with silver showed both fast and long-lasting antibacterial effectiveness against *Escherichia coli*. The silver antibacterial materials prepared in the system are promising candidates for a wide range of biomedical and general applications.

Chitosan/ZnO nanoparticle composite membranes was synthesized and characterized by [Li et al. \(2010\)](#). In their works, novel chitosan/ZnO nanoparticle (CS/nano-ZnO) composite membranes were prepared via the method of sol-cast transformation. The antibacterial activities of composite membranes were measured by the diameter of bacterial colonies, compared to a positive control and the pure CS membrane. The antibacterial activities of CS membranes for *Bacillus subtilis*, *Escherichia coli*, and *Staphylococcus aureus* were found to be enhanced by the incorporation of ZnO. CS/nano-ZnO composite membranes with 6–10 wt% ZnO exhibited high antibacterial activities by their research.

Conclusions

The current study showed that CaCO₃ nanoparticles was successfully prepared and fabricated novel biomaterials using newly synthesized CaCO₃ nanoparticles via solution mixing and film casting method. The CaCO₃ nanoparticles had been successfully incorporated into the PLA/CS matrix as the FTIR spectrum showed improved interaction between the PLA, CS and CaCO₃ nanoparticles in the composites. The fabricated composites also showed improvement in mechanical strength and 1.0 wt% CaCO₃ nanoparticles were the most optimum amount to be incorporated into PLA/CS matrix. These improvements were attributed to good attractive interaction between the composites components. Meanwhile, addition of CaCO₃ nanoparticles into the PLA-CS matrix helped to offset the effect of CS in the matrix and reduce the weight loss. However, the thermal stability seems to be also reduced as the CaCO₃ nanoparticles were introduced into the matrix. Research has demonstrated that silver (Ag) and Zinc oxide (ZnO) nanoparticles based chitosan biomaterials exhibited high antibacterial activities.

Introduction

In current advances of material sciences and technology, polymer nano composites have become the trending amongst researchers. Furthermore, with the latest invention of nano-materials, numerous blends of polymeric matrix materials with appropriate and accurate ratio of nanofiller have been reported, with improved filler/matrix interaction, and innovative procedures in polymer nanocomposites preparation. More potential applications have also been identified such as building and constructions, medical, packaging, aerospace and automotive appliances (Saba *et al.*, 2014).

During the preparation of this material, the most important factors that need to be monitored are the quality of dispersion of the nano-reinforcement particles and the interfacial interaction between the matrix and the reinforcement phase. These two factors need to be optimized through several methods and treatments. Failures might be occurred due to poor dispersion and interfacial interaction, resulting some of the findings had become not significant in the end of process. Nevertheless, many improvement have been achieved in term of the processability of material and the improved quality and properties of end results. For instance, polymer nanocomposites have been rectified as the material with improved tensile strength, heat distortion temperatures, thermal and electrical conductivities, and enhanced gas barrier properties (Utracki, 2004). To obtain in-depth knowledge of the processing and applications of polymer nanocomposites, the requirements to comprehend these properties are vital before performing further research. Besides, portions of micron sized fillers also could provide changes in certain properties. These changes were attained within the range of 3–5 wt% of nanofillers. This range was attained based on a review, stated that with just a small quantity, the addition of nano-sized layered silicates in plastics has been found to offer improvements to the above-mentioned properties. More research could be carried out to increase the usage quantity of nanofiller without compromising the good properties of the polymer matrix, since polymer nanocomposites have gained tremendous interest in both the academic and industrial research due to their advantageous and exclusive structure (Gupta and Bhattacharya, 2008).

One of the prime polymer that was typically used in plastic manufacturing process is high density polyethylene (HDPE). This material was favored due to its abundance, low price and ability to be recycled. HDPE provides good mechanical and thermal properties with fair modulus and yield strength in conjunction with high-impact strength. Hence, an improvement was needed by reinforcing this material with inorganic minerals such as clay, wollastonite, glass bead, and calcium carbonate. Based on previous research, the growth in crystalline can be attributed to the nucleating effect of nanoclay, while the motive for crystallization temperature of HDPE/nanoclay nanocomposites continue to be unchanged. In this case, the key factor was the particle–matrix interaction, which critically affects the free energy of cluster formation and the rate of nucleation, whereby the weak interaction lowers the rate of nucleation (Thabet *et al.*, 2011).

HDPE-Nanoclay Composites Preparation

High density polyethylene is one of the common commodity plastics available commercially in market. Researchers have performed several attempt to develop new composite by using this material as the matrix (Akdoğan and Bektaş, 2018). In order to prepare the polymer nanocomposites made from HDPE and nanofillers, there are three methods that can be utilized, which are solvent intercalation, in situ polymerization and melt intercalated, as presented in Fig. 1 (Ray and Okamoto, 2003).

Based on a review, a research about HDPE/nanoclay preparation through solvent intercalation had been carried out. The mixture was prepared through solution blending with sodium montmorillonite cation exchanged with protonated dodecylamine. Unfortunately, poor dispersion was obtained due to the existence of large stacks in the composites system. At that moment, the exfoliated morphology could only be obtained by applying the in-situ polymerization. Later, the idea was succeeded by using the modified oligomer. This method could facilitate the polarity between silicate layers and polymer, thus improving the dispersion of clay. By using this preparation method, a research had been carried out about the flammable

Fig. 1 HDPE-nanoclay composites method of preparation. Reproduced from Ray, S.S., Okamoto, M., 2003. Polymer/layered silicate nanocomposites: A review from preparation to processing. *Progress in Polymer science* 28 (11), 1539–1641.

properties of this material. By adding not less than 1 wt% clay, the exfoliated nanocomposites burning rate had decreased 10%–15%, due to the formation of a high performance carbonaceous-silicate char that builds up on the surface. Hence, the underlying clay had insulated the composite when the diffusion of oxygen reduced. The mass loss rate of the product also become slow (Gupta and Bhattacharya, 2008).

To quote an example for the third preparation method, which is melt intercalation, a research has been carried out about the ability to prepare nonpolar nanocomposites. This research was performed by adding cation surfactant as reactive compatibilizer. Trials towards combustion had been carried out, resulting a deduction of heat release rate by 32%. Hence, it was proven that HDPE/nanoclay was the suitable material that can be chosen for high temperature environment, such as component for automotive section (Wang *et al.*, 2001).

One of the research related to multiple preparation process had been conducted by using three cationic surfactants. These surfactants were used to alter the clay (montmorillonite) and polyethylene (PE)/maleic anhydride grafted polyethylene (PE-g-MAH)/organic-montmorillonite (Org-MMT). These nanocomposites were prepared by direct-melt blending and solution blending. Based on the intercalation behavior and microstructure analysis, the intercalation effect of nanocomposites had improved. The degree of crystallinity of composites and the crystalline thickness perpendicular to the crystalline plane was decreased with increasing amounts of PE-g-MAH. It was also found that the crystalline thickness of the sample made by the solution method was much smaller than that made by direct-melt blending. Therefore, based on the heterogeneous nucleation effect, it showed that the nanocomposite made by the solution-blending method is better than that made by the direct-melt intercalation process (Liang *et al.*, 2004).

As mentioned before, the dispersion and interaction of layers were very important to determine the performances of polymer nanocomposites. Even though previous research had concluded that the solution-blending method is better than that made by the direct-melt intercalation process, a full exfoliated clay dispersion could be achieved by adding the maleated HDPE through melt blending process, enhanced by the incorporation of mixing and shearing elements and high residence times, in the twin-screw extruder (Mehrabzadeh and Kamal, 2004). Another research also had found the same findings. Through long residence time obtained by using twin screw extruder, the effects of clay content and state of clay dispersion on the rheological, tensile properties, and flame retardancy of nanocomposites containing very small amounts of clay, in the range of 0.05–1.0 wt%, were analyzed. According to wide-angle X-ray diffraction and transmission electron microscopy, a higher degree of exfoliation for nano sized clay particles is key to enhancing the rheological, mechanical, and flame retarding properties even when small amounts of clay (less than 1%) are used (Lee *et al.*, 2007).

Hence, it can be concluded that melt compounding is a preferred technique used in HDPE/nanoclay preparation, due to the readiness of twin screw compounders and friendly towards environment because the exclusion of solvent usage. This breakthrough had stimulate the event of having more and more research to be performed. Based on several reviews, majority of research had been concentrate on material variables, such as compatibilizer, filler types/content and types of polymer. Therefore more studies were needed to rectify the influence of processing conditions, such as extruders design and configurations, internal mixers settings, temperature and pressure control as well as the processing condition optimization (Ujianto *et al.*, 2015).

Effect of Nanoclay Content

Most of electric and electronic devices were made from plastic. However, the advancement of this application oblige multi-functionality in a single material. Pristine plastic could not provide certain function needed for manufacturing requirement. To solve this problem, a multi-functional composite could be fabricated by mixing the plastics with additives, fillers, and reinforcements. Conventionally in plastic manufacturing process, additives, fillers, and reinforcements were manipulated to alter and expand certain physical and mechanical properties of matrix in composites. Fillers were used to improve modulus while reinforcement was utilized to modify the mechanical properties. Typical fillers have unfavorable geometrical features, surface area or surface chemical composition. However, this features could amend certain matrix moderately. Most of fillers were used to reduce cost by decreasing the quantity of polymer matrix, especially for those special and costly material. More than that, it could enhance the production by promoting faster molding cycles through the increment of thermal conductivity. Type of fillers also could influenced certain properties of polymer, like fibrous material could experience higher melt viscosity with the addition of fillers (Thabet *et al.*, 2011). Furthermore, shrinkage, warpage and thermal expansion also could be improved through the incorporating fillers with several types of polymer, as well as by adopting a systematic statistical optimization method (Ibrahim *et al.*, 2014).

Choosing the type of clay is very important, since a clay modifier could improve the exfoliation of clay layers in HDPE/nanoclay system. This clay modifier could become a nucleation agent, increases marginally the crystallization temperatures, and reduces the crystallite size and act as a compatibilizer (Mehrabzadeh and Kamal, 2004). More evidence had proved that different type of clay also influenced the final outcome. For instance, a local montmorillonite clay obtained from Kutch region in western part of India was blended with HDPE. Before that the clay was modified by Hexadecyl trimethyl ammonium bromide, a quaternary ammonium compound to make it organophilic. Evaluation had been made towards mechanical, electrical and thermal properties. It was found that the tensile readings was value-added, and the electrical properties also improved considerably, through the treatment of silane and titanate compounds towards the organoclay (Shah *et al.*, 2009). As for another example, a comparison of surface energy had been made between the pristine and the thermally stable phosphonium-modified montmorillonite usage on polymer/clay nanocomposites. Values of the Hamaker constant and thermodynamic work of adhesion for HDPE/nanoclay nanocomposites were the factors that need to be monitor since it was correlated with the dispersion behavior and mechanical properties (Kamal *et al.*, 2009).

Besides type of clay, the amount of clay loading also could affect the properties of HDPE/nanoclay. According to a research, the elastic modulus and tensile strength shows certain improvement by adding the nanoclays in HDPE foam, as compare with pristine HDPE foams. The best clay loading recommended was 0.5 wt% (Jo and Naguib, 2007). More research had been conducted to examine the effect of clay loading towards HDPE/nanoclay nanocomposite. The difference in this research was the existence of pine flour in the nanocomposite system. The compound was prepared through melt intercalation. Then, the compound was injected mold to prepare test specimens. Based on the results, there were an increment of flexural and tensile strength. The optimum clay loading is 1 wt%. However there was a negative effect towards impact strength, but the condition remain even though more clay was loaded (Lei *et al.*, 2007). Furthermore, some findings have been summarized, regarding the properties that should be obtained by testing the HDPE/nanoclay nanocomposites, with numerous clay loading within the range from 0 wt% (pristine HDPE) to 4 wt% nanoclay MMT. The summary stated that (Venkatesan *et al.*, 2014):

- The increment of the clay loading shall produce the increment of tensile strength as well.
- 3 wt% of MMT clay is the optimum clay loading for the impact strength and shore hardness.
- The highest the flexural strength can be attained with 3 wt% and 4 wt% of clay loading, even with the increment of cycle loading number.
- The flexural strength also increase slightly and then sustains nearly constant there off for all clay loadings during the introduction of cyclic loading.
- Mechanical properties of HDPE/nanoclay could be control by selecting the suitable amount of clay loading.

Effects of Compatibilizer and Reinforcement

In composite preparation, the usage of compatibilizer and reinforcement is very important to ensure the desired properties will be achievable.

Further cutting-edge polymer nanocomposites could be attained by extending the formulation of HDPE/nanoclay with the usage of various compatibilizer and reinforcement. The additional of natural fiber for reinforcement, such as bamboo or kenaf could bring more benefits in term of mechanical properties. To quote one example, a research had been completed towards HDPE/nanoclay/bamboo fiber, with different fraction of maleated polyethylene (MAPE) and clay loading. Based on the findings, the addition of nanoclay had reduced the resistance towards impact. However, the tensile strength, bending modulus and strength can be upgraded with the use of compatibilizer (MAPE). Since the dispersion of nanoclay had compromising the properties of HDPE/nanoclay/bamboo fiber, therefore a different technique such as pre-coating fibers might be useful to recover the properties of these polymer nanocomposites (Han *et al.*, 2008).

More research had been conducted since the usage of compatibilizer had become major interest among researcher. By manipulating the various type of modified clay and the amount of maleic anhydride (compatibilizer), the effects toward intercalation condition and mechanical properties were analyzed. According to the findings, the clay type I.30TC was preferred, and the grafted maleic anhydride HDPE had added a higher degree of intercalation in clay particles. The compatibilizer also had increased the tensile modulus, but need to be sustained at specific amount to recover the range of intercalation (Mehrabzadeh *et al.*, 2009). Another research had examine the effect of various amount of maleic anhydride grafted high density polyethylene (MA-g-HDPE) to determine the morphology of HDPE/nanoclay nanocomposites. Through spray electrostatic powder technique, an extruded composite powders were applied on treated steel surfaces, followed by curing process with specific temperature and time. Based on the scanning electron microscopy, the surface uniformity of produced coating films was analyzed and the findings indicate that by using 15 wt% MA-g-HDPE, the highest adhesion and bending strength and more surface uniformity could be achieved (Mardani *et al.*, 2014).

Applications and Recycling of HDPE/Nanoclay

The idea of using nanoclay as a filler for HDPE was made due to improve several properties and at the same time to obtain an effective cost savings solution by reducing the amount of polymer used in various type of product, such as food packaging, automotive components and so on. The improved barrier properties gained from the intercalated organic layered structure also one of the benefits that can be achieved (Cabello *et al.*, 2010). To quote one example, a research had found that the usage of nanoclay could enhanced the oxygen and water vapor transmission rates for HDPE/nanoclay nanocomposites. These properties were very suitable for packaging films and containers for food or other perishables. Moreover the use of nanoclay could provide a higher specific gravity HDPE, which is good for barrier properties even if it meant the article or film was more brittle as a result (Qian *et al.*, 2009). Besides that, HDPE/nanoclay also can be used for pipes and fittings, since the existence of nanoclay could improve the slow crack growth resistance of the nanocomposites, even if it was made from the recycled HDPE (Na *et al.*, 2017). The summary of application for this material is displayed as Fig. 2.

The addition of nanoclay also could affect the HDPE/nanoclay composites in terms of flammability and the sensitivity toward temperature. Several experiments have been performed for this material characterization, by using X-ray diffraction, transmission electron microscopy, thermogravimetric analysis, crystallinity (differential scanning calorimetry and wide angle X-ray scattering techniques), and cone calorimetry technique as well for flammability study (Szustakiewicz *et al.*, 2013). Hence, product such as

Fig. 2 HDPE-nanoclay applications. Reproduced from Cabello, J.M.L., Torres, e.g., Mas, L.C., 2010. U.S. Patent Application No. 12/159,532. Qian, G., Jarus, D., Zabrocki, V., 2009. U.S. Patent No. 7,629,406. Washington, DC: U.S. Patent and Trademark Office. Na, S., Nguyen, L., Spatari, S., Hsuan, Y.G., 2017. Effects of Recycled HDPE and Nanoclay on Stress Cracking of HDPE by Correlating Jc With Slow Crack Growth. US Department of Energy Publications, 368.

engine casing or covers should be suitable for applications. However, several factors need to be monitored, such as properties of interior plastic structures that are noticeably changed after being exposed repeatedly to sun light and rains. Such defects like loose fasteners and clips could happen if the thermal behavior was not analyzed properly (Kim *et al.*, 2011).

As for HDPE/nanoclay potential to be recycled, a research had been carried out towards the waste of HDPE/nanoclay-unmodified and organo-modified. Several findings have been clarified, such as XRD and FESEM results show a considerable effect of exfoliation and interaction organo-modified nanoclay layers in HDPE matrix. The melting temperature of HDPE/nanoclay also maintained at same level with no major shifts, according to the differential scanning calorimetry, or DSC analysis. The best behavior for the enthalpy of fusion was offered at 3 wt% clay loading for the waste HDPE/nanoclay compound. This waste nanocomposites also produced highest elastic modulus with the increment of 7.4%. However, several properties were compromised, such as tensile stress at maximum load, strain at break and tensile stress at yield were found slightly decreased in the low OMMT clay content. As for the conclusion, a better reinforcement of the waste HDPE in melt interaction method could be obtained, based on the revision of waste polymer recycling through dissolution/re-precipitation method (Hadi *et al.*, 2018).

Conclusion

This article provides a review of the injected mold HDPE/nanoclay polymer nanocomposite, in terms of preparation, effect of nanoclay, compatibilizer and reinforcement of this material. The applications and recycling issues also have been discussed. Several reviews and summaries were made from previous findings so that this article could become a good reference for future researches and manufacturing guidelines.

Introduction

Recent research on the interesting environment friendly issue has motivated the researchers to investigate biodegradable as well as economically viable bio-based composite. In bio-composite either reinforcing material or matrix material is bio-degradable (Nam *et al.*, 2011) or both are bio-degradable. These bio-degradable materials mainly grow naturally and they are directly or indirectly collected from nature. Bio-based material, in this particular case natural fiber, is mainly collected from plant's stem, leaf, seed, stalk, bast and fruit. Jute, coir, bamboo, banana, cotton, hemp, kenaf, pineapple leaf, okra, mesta, sisal and dhaincha fiber are in this categories. As they are natural, heterogeneity exists in the fiber characteristics. This heterogeneity of the fibers is controlled in the characteristics of end product, particularly mechanical and thermal properties. Many studies found that in bio-composites, fiber property is reinforced and the composite showed different mechanical and thermal criteria compared to the fiber and matrix. Therefore, each type of composite has the specific application due to their specific criteria. Moreover, bio-material has low density, high strain, high modulus of elasticity, and above all they contain OH group. Due to this OH group, they can easily absorb water and are attracted by bacteria and subsequently they become bio-degradable (Haque *et al.*, 2009, 2010). Furthermore, bio-material gives a lot of oxygen in the air during their production and emits a negligible amount of CO₂ as compared to synthetic fiber production. Therefore, bio-composite has a great impact on the life cycle, which is fully decomposed in nature or environment at a certain condition. Moreover, the use of bio-based composites is also economical as they grow naturally. Therefore, the bio-based composite can be used for several applications in small as well as large industries including household, building, vehicle, construction material, medical appliance, sports accessories and aerospace industry (Mohammed *et al.*, 2015). However, according to bio-based news jute fiber production (3300 MT) is in the 2nd position after cotton, whereas coir 1022 MT which is 4th position after wool among the natural fiber production in 2016 (Dommermuth, 2016). These types of natural fiber's properties are comparable with synthetic fiber except deviation of criteria, and less thermal stability. Thus, value added production from this natural fiber is important.

In composite, there are two parts, reinforcing material and matrix material, whereas filler is sometimes added for improved performance. Reinforcing material particularly fiber is discussed in the previous paragraph, which can be natural and manmade (not biodegradable). On the other hand, matrix material can be metallic, ceramics and polymer. In addition, there are two types of polymer matrices namely, thermoplastic (polypropylene, polyethylene, and polyvinyl chloride) and thermoset (such as polyester, acetal, phenolic, polystyrene, polycaprolactone, polylactic acid, polyhydroxybutyrate, vinyl ester and epoxy). Biodegradable matrix is also available. Based on the reinforced fiber present in the material, the composite materials can be categorized in two classes. When there is no reinforcement, it is termed as monolithic. On the other, hand when there is a reinforcement material or fiber present in a matrix material it is termed as composites such as jute-PP (polypropylene), jute-polyester and jute-epoxy. However, with more than one reinforcing material or fiber involvement is termed as hybrid composite. For example, jute-coir-PP, coir-bamboo-polyester and banana-jute-starch. The amount of fiber incorporation in the matrix depends on the fabrication method. Enormous research activities involve regarding bio-composite fabrication, characterization, comparison. There is heterogeneity in the research, the fiber has diversity in their criteria and there are different characteristics of matrices. Based on this contemplation, it is not possible to get clear idea about the design, fabrication and the final use of bio-composite. In the present article, a critical review has been made on design, fabrication, properties and application of three bio-based composites.

Design

Monolithic, composite and hybrid composite designs are used to tailor the criteria of composites. The design of the fabrication of composite depends on the criteria of fiber and matrix, fabrication method, the desire of criteria, as well as required final products characteristics. Mostly used fabrication designs based on the fiber loading are listed in Table 1. Different percentages of fiber are used for composite fabrication because criteria of the composite are dependent on the percentage of the fiber loading in the composite. In case of injection molding, fiber incorporation can be increased as compared to hand lay-up technique. In composite, reinforcement can be in the form of a particle short fiber as well as long fiber. Based on the form of fiber in the composite, the required criteria of the end product of composite are changed. Similarly, the concept of the hybrid composite is developed and showed better performance.

Fabrication

This section describes common fabrication techniques of the bio-based composite. Different methods have been used by researchers and industries for composite fabrication. Such as hand-lay-up, wet-lay-up, vacuum bag, mandrel wrapping, filament

Table 1 Design of composite based on fiber loading

Types	Design	Fiber	Matrix	References
Monolithic	PP		100%	Shahinur <i>et al.</i> (2017)
	Polyester		100%	
Composite	Jute matrix Treated jute matrix	15%, 20%, 25%, 30%, 35%, 40%, 50%		Rahman <i>et al.</i> (2008), Rahman <i>et al.</i> (2009), Shahinur <i>et al.</i> (2017)
	Coir matrix Treated coir matrix	15%, 20%, 25%, 30%, 35%		Haque <i>et al.</i> (2010), Haque <i>et al.</i> (2009)
	Banana matrix Treated banana matrix	2%–10%, 20%, 30%, 40%, 50%		Ramesh <i>et al.</i> (2014), Amir <i>et al.</i> (2017), Ogunsile and Oladeji (2016), Nagendra <i>et al.</i> (2017)

**Fig. 1** Flowchart of thermoplastic composite fabrication by injection molding.

winding, pultrusion, injection molding, hot press, compressing molding, extrusion and bladder molding. In the present article injection molding and hot press methods are discussed in detail. These two are the most commonly used methods so far throughout the industry and research sectors.

Injection Molding

In case of injection molding method first reinforcing material or bio-based fiber was first cleaned and chopped into an approximate length of 3 mm. Thereafter, dried fiber was randomly mixed with thermoplastic granules in order to prepare the composites as shown in **Fig. 1**. Both raw and treated fibers were mixed with desire matrix at different weight percentage separately. Composites were prepared by passing the mixtures through a single screw extruder machine at a constant temperature of $135^{\circ}\text{C} \pm 5^{\circ}\text{C}$. The extruded composites were cut into 15–20 cm long small pieces. All the pieces were then crushed into smaller granules using a grinding machine. The granules were dried in a vacuum oven at 65°C for 1 h and fed into an injection molding for making specimens. The dried granulates were molded according to ASTM standard for characterization (Nahar *et al.*, 2013; Shahinur *et al.*, 2017).

Hot Press

Another important composite fabrication technique is hot press method. During hot pressing, according to the design, the fiber was cleaned and chopped into certain specified length (< 5 mm or greater) or in the form of a particle. After that dried fibers were randomly mixed with thermoplastic granules (**Fig. 2(a)**) or sheet (fibers are evenly distributed in the layers of sheet) (Sayeed *et al.*, 2014) at different wt% as shown in **Fig. 2(b)**. Thereafter, the mixture was heated and pressed at melting temperature of matrix to fabricate the desired composite.

According to published literature, thermoplastic material such as acrylics, polyethylene (Sultana *et al.*, 2013), polyvinyl chloride (Saheb and Jog, 1999), polypropylene (Sayeed *et al.*, 2014; Haque *et al.*, 2009; Haque *et al.*, 2010) and polystyrene (Plackett *et al.*, 2005) matrix are used in different areas according to their individual characteristics (Nirmal *et al.*, 2015). The properties of jute, coir and banana fibers are listed in **Table 2**.

From **Table 2** it is clear that jute fiber has higher percentage of cellulose, whereas coir has higher percentage of lignin content. These raw fibers are incorporated in the composite to reinforce the specific criteria. However, for better result, sometimes natural fibers are chemically treated and physically modified. Important used chemicals are benzene diazonium salt, Cu salt, ammonium salt (Shahinur *et al.*, 2017), uric acid, potassium di chromate, sodium hydro-oxide (Sayeed *et al.*, 2014), sodium peroxide and permanganate (Jordan and Chester, 2017). Bio-fibers are also radiated or grafted for better performance of the bio-composite. Furthermore, the hydroxyl group in the bio-based fiber is responsible for high water absorption and the weak interfacial bond between the fiber and matrix. There are actually three hydroxyl groups present in a cellulose anhydrous-glucose unit of fiber as shown in **Fig. 3**.

One is a primary hydroxyl group at C_6 and the other two are secondary hydroxyl groups at C_2 and C_3 . Although the primary hydroxyl group is more reactive than the secondary groups, the salt breaks the OH group of C_6 and C_2 during the reaction. This

Fig. 2 Flowchart of thermoplastic composite fabrication using (a) granule and (b) using sheet through hot press process.

Table 2 Chemical constituent and mechanical properties of three bio-based materials/fibers

Chemical constituent	Jute	Coir	Banana
Cellulose (%)	59–61	43.44	53.45
Hemi cellulose (%)	22.1	0.25	28.56
Lignin (%)	15.9	45.84	15.42
Ash (%)	1	2.22	1
Density (gm/cc)	1.3–1.5	1.2–1.3	1.3–1.5
Fiber length mm	1.2–1.5	20–150	–
Fiber tensile strength (MPa)	400–800	220	355
Fiber modulus of elasticity (GPa)	70	6	33.8
References	Mohammed <i>et al.</i> (2015)	Haque <i>et al.</i> (2009), Haque <i>et al.</i> (2010)	Jordan and Chester (2017), Saheb and Jog (1999)

Fig. 3 Reaction group of bio-based fiber.

converts the two hydroxyl groups into related compound. The FT-IR spectroscopic analysis of the raw fiber, namely, jute (Shahinur *et al.*, 2015), coir (Haque *et al.*, 2010), and banana (Merlini *et al.*, 2011) confirms this phenomenon.

Properties

A good number of researches have been carried out on the characterization of bio-based polymer composite. In this study, mechanical, physical and thermal properties of bio-based composites are highlighted in the following sections.

Mechanical Properties

Under the mechanical properties there are tensile, flexural, toughness, hardness, ductility, fatigue strength and elasticity. In this particular study tensile, impact and hardness of the three bio-based composite are described as follows.

Tensile properties

The tensile strength of raw and treated fiber reinforced bio-composites for three different fibers is shown in Table 3. Tensile fracture behavior of composites is ductile. For the raw fiber reinforced composites, the tensile strength decreased with fiber loading, which is supported with the findings of Haque *et al.* (2010) and vice versa (Nam *et al.*, 2011). When fiber load is increased, the weak interfacial area between the fiber and matrix increased, as a result, tensile strength decreased. After chemical treatment, the reaction took place deep down in the specimen, which improved the mechanical properties of the related composites. From Table 3 it is

Table 3 Mechanical properties of bio-based polymer composite

Bio-composite	Tensile strength (MPa)	Young's Modulus (GPa)	Flexural strength (MPa)	Flexural modulus (GPa)	References
Coir-PP	22–27	1.25–3.5	46–50	1.5–3.5	Haque <i>et al.</i> (2010)

Table 4 Impact, hardness, and water absorbance of jute, coir, and banana bio based polymer bio-composites

	Impact Kg/m ²	Hardness Rockwell L	Water absorbance %	References
Polypropylene	19/22.34	66.4	0.09	
Jute	25–85 (Ranganathan <i>et al.</i> , 2015)	78–97 (Sultana <i>et al.</i> , 2013)	0.7–1.26	Khan <i>et al.</i> (2010), Rahman <i>et al.</i> (2008)
Treated jute	18–24	77–87	0.73–1.22	
Coir	35–60	80–90	0.3–1.7	Haque <i>et al.</i> (2010), Haque <i>et al.</i> (2009)
Treated coir	40–60	90–105	0.3–0.7	
Banana	1.2–1.8	60–66	15–30	Mishra <i>et al.</i> (2000)
Treated banana	0.9–1.5	66–72	10–25	
Polyester				
Treated jute	40–160		6.13	Deb <i>et al.</i> (2017)
Treated coir	40–55	85–95		Haque <i>et al.</i> (2010)
Treated banana	32–147		1.5–4.74	Muktha and Keerthi Gowda (2017)

cleared that, due to chemical treatment the related composites improve the tensile strength as well as Young's modulus. The stronger fiber shows more fiber pull out compared to the weaker fiber composites.

Flexural properties

Flexural strength and flexural modulus of raw and treated bio-based fiber composites for different fiber are listed in **Table 4**. The data are collected from different research articles and that data are represented as range based on obtained flexural properties. As the flexural fracture behavior of the composites is also ductile, the flexural strength increased with fiber loading for some fiber composite (Haque *et al.*, 2009). However, there was a decrement for certain fiber loaded composites (Shahinur *et al.*, 2017; Nahar *et al.*, 2013). Furthermore, from **Table 3** it can be concluded that after chemical treatment the flexural properties of the related composites are improved compared to untreated fiber composite for PP as well as polyester matrix composites. In case of high flexural strength there is high fiber pull out and vice versa.

Impact properties

Variation of the Charpy impact strength for both raw and chemically treated three different bio-based fiber composites are listed in **Table 4**. Impact strength increased with fiber loading (Haque *et al.*, 2010; Rahman *et al.*, 2008). However, there was a decrement in the impact property for some specific fiber loaded (Chattopadhyay *et al.*, 2011).

Hardness and water absorption characteristics

Table 4 shows the hardness of various manufactured composites for three different bio-based fiber, namely jute, coir and banana. Average hardness increased with chemical treatment of fiber (**Table 4**) and fiber loading (Haque *et al.*, 2010). This is due to the increase of stiffness of the respective composites. The hardness of jute-PP composite is about 66.4, which is increased in chemically treated fiber composite. Similar trend is found for coir as well as banana polymer composite as shown in **Table 4**.

Water absorption characteristics of manufactured composites are shown in **Table 4**. Water absorption (%) generally increases with an increase in fiber loading (Haque *et al.*, 2010). As mentioned earlier, the hydroxyl groups in bio-fiber, namely, jute, coir and banana, are responsible for high water absorption. With the increase in fiber loading, the number of hydroxyl groups in the composites increased, which in turn increased the water absorption. Chemically treated bio-fiber reinforced composites had lower

Table 5 Thermal properties of jute, coir and banana bio-based polymer composites

Item	Thermal stability	References
Jute matrix	250–365°C	Kabir <i>et al.</i> (2012), Kabir <i>et al.</i> (2013), Rahman <i>et al.</i> (2008)

Jute based composite	Coir based composite	Banana based composite
Building panels, roofing sheets, door frames, door shutters, transport, packaging, geotextiles, and chipboards, absorbent cotton, storage device, furniture, transportation, house hold accessories, Bio-degradable shopping bag.	Building panels, flush door shutters, roofing sheets, storage tank, packing material, helmets and postboxes, mirror casing, paperweights, projector cover, voltage stabilizer cover, a filling material for the seat upholstery, brushes and brooms, ropes and yarns for nets, bags, and mats, as well as padding for mattresses, seat cushions	Biodegradable sanitary napkin and diaper (Barman <i>et al.</i> , 2017).

water content compared to the raw ones, as the treatment decreased the number of hydroxyl groups in the resultant composites. Water absorption (%) decreased over the raw fiber polymer composites.

Thermal Properties

Thermal stability of the composite depends on the matrix as well as fibers (jute, coir and banana) that we use as reinforcing material. For example, HDPE, MAGPP, epoxy, polyester, and starch matrix sustain at 525°C, 450°C, 400°C (Bansal and Agarwal, 1984), 245–289°C (Bora *et al.*, 2013) and 250°C respectively. Whereas jute, coir and banana fiber are thermally stable at 25–250°C. The related thermal stability of the selected bio-based composites is listed in Table 5. Thermal stability of jute composite is 25–265°C whereas it is increased after chemically treated jute composite. The similar phenomenon is observed in the case of raw and treated coir as well as banana fiber as shown in Table 5. It is clear that the range of thermal stability for treated composite, is increased due to specific chemical modification of natural fiber. The upper range of thermal stability depends on the matrix material as well as chemical concentration.

Applications

According to Mohammed *et al.* (2015) bio-fiber is used in the house hold industry and car interior. Due to the advantages of bio-composites such as biodegradability, high stiffness, cheap and lightweight give them appropriateness in the various application in engineering application such as building industries, structural concrete elements as reinforcement, while coir fiber composites have been used in roofing components in order to replace asbestos. In addition, bio-fiber composite products in building applications like bar, sheets (plain, corrugated) and boards are light in weight and are appropriate for use in roofing, ceiling, and walling for the construction of low-cost houses. Due to good sound absorption properties, bio-fiber composites are used in theater and conference hall. Due to good thermal property the bio-based composites are used in agriculture sector in cold region. Table 6 shows the various applications of cellulose fiber in industry, construction, and other industries.

Conclusion

Natural fiber-based composites are eco-friendly compared to fully synthetic composite. However, design, fabrication, properties and applications of different categories of bio-based composites are explained in this article, sustainability of these types of bio-based composite is also an important issue for the next generation regarding green globalization. Sustainable properties such as CO₂ emission, recycle fraction, safety and water usage of these bio-based composites are needed to analyze regarding the sustainability of bio-based composite. Nevertheless, these sustainable properties particularly CO₂ emission is related to the electricity consumption for final product development. Natural materials absorb CO₂ and emit O₂ during the primary material, namely, fiber production, which has a positive impact on the total CO₂ emission of the bio-based composite production. If the composite becomes sustainable the bio-based product will be sustainable indeed. Based on the above contemplation sustainable properties are the important issues for the green revolution. Thus, this is an open research topic for future research.

Introduction

Recently, natural fibers have received a great interest due to their possible use in manufacturing environmental friendly composites materials along with many intrinsic properties such as strength, thermal, water barrier and biodegradability (Kumar *et al.*, 2013). The worldwide availability of natural fibers is accountable for the new polymer materials and industrial research, and the exploration for a maintainable technology. Natural fibers were presented with the intention of yielding lighter composites, together with lower costs lower density as compared to the glass fiber, which confirms the production of lighter composites (Abdul Khalil *et al.*, 2008). Various conventional petroleum based polymers are used widely with natural fibers such as jute, bamboo, banana, hemp, sisal, coir, wood, kenaf etc., (Akil *et al.*, 2011). Recently, the rapidly expanding use of composite components in automotive, construction, sports and leisure, and other mass production industries, has been focused on sustainable and renewable reinforced composites (Azwa and Yousif, 2013). Among all natural fibers, kenaf fibers have received much attention in the composite industry due to its potential as polymer reinforcements. Kenaf fibers are becoming increasingly popular in Malaysia as one of the natural materials that may contribute to the development of environmental friendly resources for the automotive, food packaging, furniture and sports industries. In recent times, it has been used as an alternative to wood in pulp and paper industries in order to help preserve forests, and as non-woven mats, it has been applied in industries such as automotive, textiles, and fiberboards. In the composite industry, mature kenaf fiber have been employed as fiber reinforcements to various matrices. Studies have shown that the addition of kenaf fibers have improved the mechanical properties of neat polymers (Azwa and Yousif, 2013). Kenaf fiber is extracted from the bast of the annual fast growing plant named *Hibiscus cannabinus*. The main constituents of kenaf are cellulose (45–57 wt%), hemicelluloses (21.5 wt%), lignin (8–13 wt%), and pectin (3–5 wt%). Kenaf fibers having good mechanical properties and thermal properties compare to the other types of natural fibers when it's Blend with PP (Jeyanthi and Janci Rani, 2012). Kenaf is one of the natural (plant) fibers used as reinforcement in Polymer Matrix Composites (PMCs). Kenaf has been found to be an important source of fiber for composites, and in other industrial applications (Karnani *et al.*, 1997). It is well known as a cellulosic source with both economic and ecological advantages; in 3 month (after sowing the seeds), it is able to grow under a wide range of weather conditions, to a height of more than 3 m and a base diameter of 3–5 cm (Aziz *et al.*, 2005). Kenaf filaments consist of discrete individual fibers, of generally 2–6 mm. Each layer is composed of cellulose embedded in a matrix of hemicellulose and lignin; a structure that is analogous of artificial fiber reinforced composites. Scientists state that the overall properties of kenaf fiber depend on the individual properties of each of its components (Rouison *et al.*, 2004). The strength and stiffness of the fibers are provided by cellulose components via hydrogen bonds and other linkages. Hemicellulose is responsible for biodegradation, moisture absorption, and thermal degradation of the fibers. On the other hand, lignin (pectin) is thermally stable, but responsible for the UV degradation of the fibers. To make kenaf a successful alternative crop, it must be incorporated into value-added products. People have skillfully made use of kenaf from ancient times, traditionally as ropes, canvas, sacking, and more recently, kenaf has been used as an alternative raw material in place of wood used in pulp and paper industries to avoid the destruction of forests. It has also been used to make non-woven mats in the automotive industry and textiles. About 35% of kenaf is bast fiber, which is suitable for paper, textiles, and rope; and about 65% is core (Lee and Mark, 2001). Kenaf is presently being used in paper production on a very limited basis. Various uses of the bast fibers have been explored, such as in the making of industrial socks to absorb oil spills, as well as making woven and non-woven textiles. The kenaf bast fiber is known to have the potential as a reinforcing fiber in thermoplastic composites, because of its superior toughness and high aspect ratio in comparison to other fibers. A single fiber of kenaf can have a tensile strength and modulus as high as 11.9 GPa and 60 GPa, respectively (Karnani *et al.*, 1997). Rowell *et al.* (1999) studied the potential of kenaf as a reinforcing fiber in a polypropylene matrix and compared the mechanical properties with other commonly used composite systems. Kenaf core fibers are also used in product applications such as animal bedding, summer forage, and potting media (Ramaswamy *et al.*, 2003). Kenaf fiber has potential as reinforcement filler in polymer matrix composite (PMC). The purpose of producing PMC is to create a new material that has better properties compared to their individual material. Kenaf fiber can generally be classified into two types. The first type is the outermost layer known as bast while the second type is the inner part, known as core. The core is very soft, hollow and suitable for application as organic filler in plastic, while bast fiber has hard properties and is suitable for blending with plastic, textile industry and also fiberglass technology applications. Kenaf fiber is also used as reinforcement for plastic and synthetic product, cosmetic product, organic filler and medicine. Besides that kenaf fiber is also environmental friendly (Salleh *et al.*, 2014).

Due to environmental concern, kenaf fiber is widely used as filler in composites materials. However, kenaf fiber based composites suffer from lower physico-mechanical properties compared to synthetic fiber reinforced composites. In an attempt to solve these problems, kenaf fibers is chemically treated with suitable chemicals or combined with a stronger synthetic or natural

fiber to form a hybrid formulation which is then incorporated in the polymer matrix. This will produce chemically modified or hybrid composites that take full advantages of the best properties of the constituent fibers and thereby an optimized, superior and economical composite can be obtained. Hybrid or modified natural fiber polymer composites thus provide designers freedom of tailoring composites formulations and achieving properties in a more cost-effective way that is less likely to be attained in binary systems containing one type of fiber dispersed in the matrix (Thakur *et al.*, 2014). Using a hybrid composite that contains two or more types of different fibers, the advantages of one type of fiber could complement what are lacking in the other. As a consequence, a balance in performance and cost could be achieved through proper material design. In this respect, kenaf, wood and coir fiber have the highest potential as hybrid polymer reinforcements (Akil *et al.*, 2011).

Kenaf Fiber as Reinforcement in Polymer Bio-Based Composites

The main disadvantage encountered during the addition of natural fibers, including kenaf fiber into a polymer matrix, is the lack of good interfacial adhesion between the two components, which results in poor properties in the final product (Tserki *et al.*, 2006). Polar hydroxyl groups, on the surface of the kenaf fiber, have difficulty forming a well bonded interphase with a relative nonpolar matrix; as the hydrogen bonds of the fiber surface tend to prevent the wetting of the filler surface. Furthermore, the incorporation of kenaf fiber as filler in a polymer matrix is often associated with agglomeration, as a result of insufficient dispersion caused by the tendency of fibers to form hydrogen bonds with each other (Liu *et al.*, 2004). Fiber-matrix interfacial adhesion can be improved with many chemical modifications of the fiber and one of the familiar and effective modifications applied to kenaf fiber, is an alkaline treatment based on sodium hydroxide (NaOH) (Edeerozey *et al.*, 2007). Humidity aging is widely recognized as one of the main causes of long-term failure of an organic matrix exposed to the atmosphere; or in contact with an aqueous media. There are several recognized modes of humidity aging, namely plasticization of the matrix; differential swelling related to concentration gradients, embrittlement linked the degradation of the macromolecular.

Kenaf Fiber as Reinforcement in Hybrid Bio-Based Composites

The incorporation of several different types of fibers into a single matrix has led to the development of hybrid bio-based composites. The behavior of hybrid composites is a weighed sum of the individual components in which there is a more favorable balance between the inherent advantages and disadvantages. Also, using a hybrid composite that contains two or more types of fiber, the advantages of one type of fiber could complement with what are lacking in the other. As a consequence, a balance in cost and performance can be achieved through proper material design. The properties of a hybrid composite mainly depend upon the fiber content, length of individual fibers, orientation, extent of intermingling of fibers, fiber to matrix bonding and arrangement of both the fibers. The strength of the hybrid composite is also dependent on the failure strain of individual fibers (George *et al.*, 2001). Maximum hybrid results are obtained when the fibers are highly strain compatible. The term hybrid effect has been used to describe the phenomenon of an apparent synergistic improvement in the properties of a composite containing two or more types of fiber. The selection of the components that make up the hybrid composite is determined by the purpose of hybridization, requirements imposed on the material or the construction being designed. The problem of selecting the type of compatible fibers and the level of their properties is of prime importance when designing and producing hybrid composites. The successful use of hybrid composites is determined by the chemical, mechanical and physical stability of the fiber/ matrix system.

Processing of Kenaf Fiber

In order to increase the interfacial interaction between kenaf fiber and polymer matrix of a kenaf/polymer biocomposites, the fiber is generally chemically modified with various chemical regents. The chemical modifications have been reported in earlier studies, which include alkaline treatment, silane treatment, isocyanate treatment, and acetylation (George *et al.*, 2001). Some other chemical treatments may also be effective to kenaf fiber, which is often used to treatment of many natural fibers. These treatments are- benzoylation, acrylation and acrylonitrile grafting, maleated coupling agents, permanganate and peroxide treatment. Most of the chemical treatment remove hydroxyl group from the natural fiber or to form bond with hydroxyl group.

Alkaline Treatment

Alkaline treatment is one of the most widely used chemical treatments for natural fibers, especially the kenaf fiber when reinforcing thermoplastics and thermosets (Edeerozey *et al.*, 2007; Li *et al.*, 2007). This modification is carried out by immersing the fibers in a NaOH solution for a period of time (Li *et al.*, 2007; Bogoeva-Gaceva *et al.*, 2007). The important modification that is done by alkaline treatment is the disruption of hydrogen bonding in the network structure, thereby increasing surface roughness. This treatment removes certain hemicelluloses, lignin, wax and oils covering the external surface of the fiber cell wall;

depolymerizes cellulose, and exposes the short length crystallites. Alkaline treatment leads to fibrillation of the fiber bundles into small fibers.

It is reported that alkaline treatment has two effects on the fiber: (1) It increases surface roughness, resulting in better mechanical interlocking; and (2) it increases the amount of cellulose exposed on the fiber surface, thus increasing the number of possible reaction sites.

Silane Treatment

Silane is used as coupling agents to allow natural fiber to adhere to a polymer matrix, thus stabilizing the composite material. Silane coupling agents may reduce the number of cellulose hydroxyl groups in the fiber-matrix interface. In the presence of moisture, the hydrolysable alkoxy group leads to the formation of silanols. The silanol then reacts with the hydroxyl group of the fiber, forming stable covalent bonds to the cell wall that are chemisorbed onto the fiber surface. The reaction schemes are given as:

Silane treatment has been introduced to kenaf fiber by previous researchers over the past few years (Huda *et al.*, 2008). Magnificent results were recorded for treated composites, in terms of interfacial adhesion between kenaf filler and the polymer matrix.

Acetylation

The acetylation of plants is a well-known esterification method of introducing plasticization to cellulosic fibers. Acetylation has been extensively applied to wood cellulose to stabilize the cell wall, improving dimensional stability and environmental degradation. Acetylation is based on the reaction of the cell wall hydroxyl groups of lignocellulosic materials, with acetic or propionic anhydride at an elevated temperature (usually without a catalyst) (Dhakal *et al.*, 2007). The reaction scheme is given as follows:

Acetic acid (a by-product from the reaction) must be removed before the fibers are used. The hydroxyl groups that react with the reagent are those of lignin and hemicelluloses (amorphous material), while the hydroxyl groups of cellulose (crystalline material), being closely packed with hydrogen bonds, prevent the diffusion of the reagent and thus result in very low extents of reaction. It has been shown that etherification improves the dispersion of fibers in a polymer matrix, as well as the dimensional stability and interface of the final composites (Edeerozey *et al.*, 2007; Li *et al.*, 2007).

Manufacturing of Kenaf Composites

Kenaf and EFB fiber with ranges of 2–3 mm was purchased from National Kenaf and Tobacco Board, Kubang Kerian Kelantan and Poly Region (M) Sdn. Bhd respectively. TT Biotechnologies Sdn. Bhd, Penang, Malaysia supplied polylactic acid (PLA). Both fibers were cut in Institute of Tropical Forestry and Forest Products (INTROP), UPM Serdang into an around length of 2 mm by using a ring knife flaker. To obtain uniform size of fiber, these jute fibers that been cut were then sieved manually using a very small size sieve (0.6 mm). Fibers were dried at open-air under direct sunlight for few days. The fibers were mixed with polylactic acid (PLA) granules using Brabender mixer machine thoroughly and homogeneously. The ratio used for fiber to PLA was 60:40 with 1:1 ratio between kenaf and EFB fibers. According to ASTM 638 and 790 standards design of mold fabrication and desire composite thickness were made. The composites were fabricated using a hot press machine. Manual hydraulic press was used to press the mold until the pressure reached 1000 psi. Temperature was set was at 160°C for both upper and lower heater and the mold was heated for 5 min. The mold was cooled to room temperature in order to prevent shrinkage during extraction of the composite.

Characterization of Kenaf Composites

The machinery Industrial Co. Ltd. cutter was used to cut samples biocomposite into ASTM standard dumb bell shape from the flat sheet samples for tensile test. The test was conducted using ASTM D 638-03 method and INSTRON 8821S (INSTRON, USA) universal testing machine. According to ASTM D790-03, flexural test was performed using the same machine mentioned above. For impact test, notched biocomposite specimen was attached horizontally and supported unclamped at both ends. The hammer was released and allowed to strike through the specimen. The impact energy in Joules (J) was obtained from the machine. Impact strength was then calculated by dividing the impact energy with length of the notch. The water absorption test of prepared biocomposites was carried out according to ASTM D 570-99. Structural and thermal properties of composites were characterized using a Perkin-Elmer 1600 Fourier transform infrared spectrometer, JSM-5510 JEOL scanning electron microscope, thermogravimetric analyzer, differential scanning calorimeter and PAN analytical X-Ray diffractometer.

Structural Analysis of Kenaf Composites

Fourier Transform Infrared Spectrometric (FTIR) Analysis

Fig. 1 shows the FTIR spectra of kenaf and EFB fiber. The broad peaks at the region of $3600\text{--}3070\text{ cm}^{-1}$ for all spectra were corresponding to the presence of free -OH groups, while the peak at 2946 cm^{-1} attributed to C-H stretching. The absorption peak at 1740 cm^{-1} and 1622 cm^{-1} due C=O and C=C stretching band (Islam *et al.*, 2017). On the other hand, the peaks at 1250 cm^{-1} and 1030 cm^{-1} represent C-O stretching. All characteristic absorption peaks as mentioned earlier confirmed the presence of polymeric constituent such as lignin, cellulose and hemicelluloses in the fiber.

Scanning Electron Microscopy (SEM)

Fig. 2 shows SEM micrographs of the tensile fractured surfaces of EFB/PLA, kenaf/PLA and EFB/kenaf/PLA composites. Surface interaction and adhesion between fiber and polymer matrix increased after fiber hybridization (Yousif *et al.*, 2012). No significant changes were observed on the micrographs of hybrid fiber composite. However, smooth fractured surface was produced after the hybridization of two fibers, which illustrate good adhesion of fibers to polymer matrix.

Fig. 1 FTIR spectra of kenaf and EFB fiber.

Fig. 2 SEM micrographs of (a) EFB/PLA bio-based composite, (b) kenaf/PLA bio-based composite and (c) EFB/kenaf/PLA hybrid bio-based composite.

Fig. 3 XRD patterns of (a) EFB/PLA bio-based composite, (b) EFB/kenaf/PLA hybrid bio-based composite and (c) kenaf/PLA bio-based composite.

Good adhesion of polymer matrix and fiber plays a key role in enhancing the mechanical properties of composites. This result reflected the improvement of mechanical strength upon fiber hybridization. Therefore, it can be concluded that incorporation of two fibers proposed good wettability properties, which decreased the formation of voids at the fibers-polymer interface and formed composites with high stiffness and strength leading to high storage modulus (Kruk *et al.*, 1997).

X-ray Diffraction Analysis

Fig. 3 shows the XRD patterns of EFB/PLA, kenaf/PLA and hybrid EFB/kenaf/PLA bio-based composites. The crystallinity values of EFB/PLA, kenaf/PLA and EFB/kenaf/PLA bio-based composites were 73.14%, 71.71%, and 74.27% correspondingly. As compared to single fiber/PLA composites, the crystallinity of hybrid EFB/kenaf/PLA composites was higher. Other than that, a new peak (2θ) at 35.0° was detected for the hybrid composites. This indicates that the crystallinity and stiffness of composites were increased slightly after fiber hybridization which led to improved mechanical strength.

Mechanical Properties of Kenaf Composites

The quality of material is classified in terms of mechanical characteristics, such as tensile strength, strain properties, impact properties and compression properties. These properties are important to determine material ability under extreme and critical conditions. Recently several studies have been performed on kenaf fiber composite, in order to fully understand its mechanical behavior in engineering applications. Some of the mechanical properties of kenaf fiber reinforced composites that important to determine such as ultimate tensile strength, fracture strain, flexural modulus and impact strength. Generally, the tensile and flexural properties of kenaf reinforced composites vary depending on the type of fiber, its orientation, content, and the type of plasticizer used. Statically, the tensile strength of kenaf reinforced composites were approximately 223 MPa in samples with a fiber fraction of 70.

Figs. 4 and **5** represent the tensile modulus and tensile strength of EFB/PLA, kenaf/PLA and EFB/kenaf/PLA composites respectively. **Fig. 4** shows that the tensile strength dramatically decreased when fiber was changed from EFB to kenaf. After hybridization of fiber, the strength of hybrid biocomposite was found to be higher as compared to that of single kenaf fiber biocomposites. However, it was still lower than single EFB fiber biocomposite. The same result was also found for the tensile modulus of the biocomposites as shown in **Fig. 5**. The modulus was found to be decreased from 431 to 321 MPa and the modulus was increased to 345 MPa after hybridization. Both tensile strength and modulus values indicate that the hybridization of fiber was capable to produce biocomposite with optimum tensile properties. This in turn proved that the great mechanical possessions of EFB fiber were able to support the low mechanical properties of kenaf fiber. The strong bonding between the matrix and fiber will lead to improve interfacial adhesion between them and therefore a higher transfer of stress from the matrix to the fibers during tensile testing (Kruk *et al.*, 1997; Pickering *et al.*, 2016).

Figs. 6 and **7** represent the flexural modulus and flexural strength of EFB/PLA bio-based composite, kenaf/PLA bio-based composite and EFB/kenaf/PLA hybrid bio-based composite. **Fig. 6** shows that the flexural strength was radically increased when fiber changed from EFB to kenaf. However, after hybridization of fiber, the strength of the hybrid biocomposite was found to be higher as compared to that of single BFB fiber biocomposite. However, it was still lower than single kenaf fiber biocomposite. The same result was found for the flexural modulus of the composites as shown in **Fig. 7**. The modulus was found to be increased from 3.9 to 4.8 GPa and decreased to 3.6 GPa after hybridization. This rise may be described by a better fibers-matrix interaction under the compressive stresses during bending, developed in the transverse section of the flexural specimens (Joshi, 1983). In general, the

Fig. 4 Tensile strength of pure PLA, EFB/PLA bio-based composite, kenaf/PLA bio-based composite and EFB/kenaf/PLA hybrid bio-based composite.

Fig. 5 Tensile modulus of pure PLA, EFB/PLA bio-based composite, kenaf/PLA bio-based composite and EFB/kenaf/PLA hybrid bio-based composite.

Fig. 6 Flexural strength of pure PLA, EFB/PLA bio-based composite, kenaf/PLA bio-based composite and EFB/kenaf/PLA hybrid bio-based composite.

Fig. 7 Flexural modulus of pure PLA, EFB/PLA bio-based composite, kenaf/PLA bio-based composite and EFB/kenaf/PLA hybrid bio-based composite.

Fig. 8 Impact strength of pure PLA, EFB/PLA bio-based composite, kenaf/PLA bio-based composite and EFB/kenaf/PLA hybrid bio-based composite.

best fiber content depends with the nature of fiber matrix interfacial, fiber aspect ratio, processing techniques, fiber and matrix adhesion, fiber agglomeration, and so on (Hassan *et al.*, 2017).

Fig. 8 represents the impact strength of EFB/PLA bio-based composite, kenaf/PLA bio-based composite and EFB/kenaf/PLA hybrid bio-based composite. Impact strength sharply decreased when EFB fiber changed to kenaf. However, after hybridization of fiber, the impact strength of biocomposite was almost similar as single kenaf fiber biocomposite. This proves that hybridization of fiber was not capable to support the low impact properties of kenaf fiber.

Water Absorption Behavior

Water absorption test was carried out for EFB/PLA, kenaf/PLA and EFB/kenaf/PLA hybrid bio-based composites and the results were shown in **Fig. 9**. It was observed that water absorption of biocomposites was increased for the first 8 days, after that it almost became constant. Hybrid fiber biocomposites had the highest percentage of water absorption as compared to single fiber biocomposite. This might be due to the hydrophilic properties of fiber which increased upon mixed up of two different fibers. So, hybrid fiber composite absorbed more water compared to single fiber biocomposite (Pickering *et al.*, 2016).

Thermal Properties of Kenaf Composites

Thermogravimetric Analysis (TGA)

Thermal stability of EFB/PLA, kenaf/PLA and EFB/kenaf/PLA bio-based composites were measured through TGA test analysis and are shown in **Fig. 10**. It can be seen from TGA thermogram that the weight of all biocomposites slight decreased in the range 55–135°C. This could be explained by the existence of residual water in the composites that was gradually released at above 100°C (Joshi, 1983). It was also observed that the onset temperature of thermal degradation of EFB/PLA and EFB/kenaf/PLA bio-based composites was around 240°C, however this temperature for kenaf/PLA biocomposite was at 270°C. This is due to better interaction and dispersion of kenaf

Fig. 9 Water absorption of EFB/PLA bio-based composite, kenaf/PLA bio-based composite and EFB/kenaf/PLA hybrid bio-based composite.

Table 1 Some potential application of natural fiber biocomposites

<i>Types of fiber</i>	<i>Application</i>
Kenaf	Package shelves
Kenaf and flax mixture	Door panel and Package trays inserts
Coconut fiber	Back cushions, seat bottoms and head restraints
Cotton	Sound proofing
Abaca	Under floor body panel
Wood fiber	Seatback cushion and sliding
Corn	Mounts tire

Note: Holbery, J., Dan, H., 2006. Natural-fiber-reinforced polymer composites in automotive applications. JOM 58 (11), 80–86.

was found that standard PLA resins are suitable for the manufacture of kenaf fiber bio-composites with useful engineering properties (Hassan *et al.*, 2017). Some of the specific application of kenaf composite as follows:

- Aerospace industry.
- Sporting Goods Industry.
- Automotive Industry (panels, frames, dashboards, body repairs).
- Home Appliance Industry.
- Sinks, bathtubs, hot tubes, swimming pools.
- Boat hulls.
- Golf clubs, fishing poles, hockey sticks &
- Electrical boxes, circuit breakers, contacts etc. (Fig. 12, Table 1).

Conclusion and Future Perspective

Kenaf based biocomposite is creating a great opportunity for engineering applications because of its exceptional properties and environmental friendly credibility. Present discussion reveals that a biocomposite with good properties could be useful and successfully improved using kenaf and EFB fibers as the filler for the PLA matrix via melt blending method. Mechanical test results indicated that high mechanical properties of one fiber were capable to support low mechanical properties of another fiber. X-ray diffraction pattern shows that the percent crystallinity of biocomposites significantly increased after hybridization. On the other hand, hybridization of fibers had no significantly influence on the thermal properties of the biocomposites. The percentage of water absorption of hybridized biocomposites was higher than the single fiber biocomposite. The morphology of biocomposites was also not much effected for fiber hybridization. The presence of two different fibers proposed good wettability properties, which decreased the development of voids at the fibers-polymer interface and created composites with high stiffness and strength. Kenaf fiber found to be an alternative source to substitute conventional or any other synthetic fiber composites. Chemical modification and processing techniques are one of the most important steps for producing better biocomposites. The application of kenaf based biocomposite as an alternative composite material, especially in automotive, aerospace, home appliance, building and construction industry. The manufacturing of kenaf composites can be open the door of new jobs in the urban and countryside. In order to fulfill market demands, more critical research work are required on appropriate manufacturing process and commercialization of biocomposites.

Materials Selection Charts for Designing Products With Biocomposites

Darshil U Shah, University of Cambridge, Cambridge, United Kingdom

Introduction

Despite the tremendous interest and vivid research in natural fiber composites for over two decades, to date, they have been successfully established only in the automotive industry for nonstructural interior panels, and the construction market for mainly house deckings (Shah, 2013; Carus *et al.*, 2014). While it is clear that there is great scope for plant fibers to be exploited as composite reinforcements, it is often suggested (Shah, 2013; Wambua *et al.*, 2003; Pickering, 2008) that the critical aspects limiting the wide industrial applications of biocomposites relate to:

- The variable and often inferior mechanical properties of plant fibers in comparison to synthetic fibers like E-glass, aramid and carbon,
- The lack of – or at least limited – empirical data on critical atypical loading conditions such as off-axis, multiaxial, high-strain rate, fatigue and creep loading,
- The inadequate – or unknown – performance effects of environmental conditions such as humidity/moisture and temperature/fire,
- The limited availability of natural fiber preforms in specific architectures (e.g., unidirectional or multiaxial fabrics),
- The limited options for biobased matrices with reasonable properties and processing characteristics.

Arguably, another key and long-overlooked aspect is the lack of comprehensive materials selection databases on natural fiber composites. The consequence is that biocomposites may not be on the radar of engineers and product designers in all relevant industries as viable alternative materials.

Materials Selection Processes

Materials selection is an integral part of the product design and development process (Fig. 1). To manufacture *products* that perform their *function* in specified *operating conditions* over their *design life*, appropriate materials need to be employed. Typically, the selection criteria for materials choice are defined by the component function, objective, and constraint. Invariably, the material processability and part manufacturability, dictated by the shape, reproducibility, and assembly of the final component, may also affect the materials choice. Due to the large variety of materials and associated manufacturing processes available, the selection of materials for a given component may be a challenging task. Indeed, if the selection process is not rigorous, the designer may opt for an inappropriate material or more possibly, overlook an attractive alternative material. Utilizing systematic materials selection processes is therefore essential.

Numerous materials selection techniques have been developed over the years (Ashby, 1992; Kutz, 2002; Jahan *et al.*, 2010), all of which rely on a large data bank of materials and their properties. The two key steps in materials selection are *screening* and *ranking*, which are part of the conceptual design stage of the design process (Fig. 1) (Ashby, 1992; Kutz, 2002; Jahan *et al.*, 2010). Screening enables to quickly narrow the field of possible materials to a manageable few while ranking narrows the choices further and then evaluates and ranks the choices to identify the optimal materials.

Ashby's materials selection chart method

One of the most popular techniques for initial screening of materials is the materials selection chart method, pioneered and popularized by Prof Mike Ashby. Ashby (1992) compares the relative performance of a variety of materials for a specific constructive function by using performance indices as design criteria. Materials screening, on the basis of these performance indices, is best achieved by plotting the performance indices that are typically a mathematical combination of material properties on each axis of a materials selection chart, also known as an Ashby plot. Individual materials or material subclasses appear as balloons that define the range of their properties. Ashby plots, such as the one presented in Fig. 2, are very useful for four key reasons (Ashby, 1992, 2008):

- (1) They allow quick retrieval of the typical properties of a particular material,
- (2) They allow quick comparison of the properties of different materials, revealing their comparative efficiencies,
- (3) They facilitate the selection of the materials/manufacturing processes during the product design stage, and
- (4) They enable substitution studies exploring the potential of one material to replace another.

A list of useful materials performance indices can be found in Ashby (1992). Generally, minimizing material weight (density ρ), cost $C_m\rho$, and/or eco-impact $I_e\rho$ are key objectives for industrial products. The key mechanical parameters, defined by the component function and constraint, are typically stiffness E and strength σ . Following Ashby (1992), the critical material performance indices that need to be maximized for a lightweight beam/plate loaded in pure tension are specific tensile stiffness

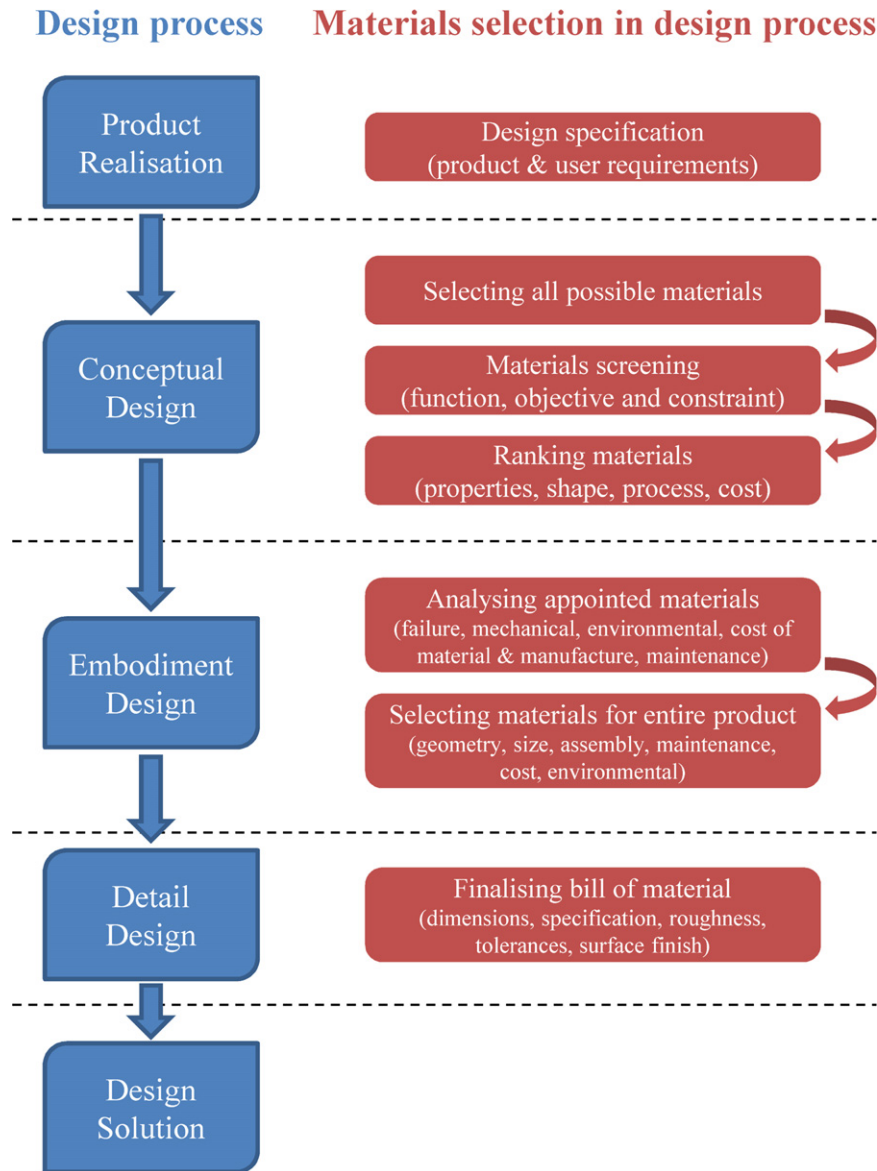

Fig. 1 Key steps in materials selection through various stages of product design.

E/ρ and specific tensile strength σ/ρ . For a lightweight beam/plate loaded in bending mode, specific flexural stiffness $E^{1/3}/\rho$ and strength $\sigma^{1/2}/\rho$ need to be maximized. Similarly, materials performance indices can be determined for vibration-limited design, fatigue-limited design, damage-tolerant design, thermal, thermomechanical, electrical, electromechanical design, to name a few.

Literature on Materials Selection Methods for Plant Fiber Composites

A survey of current (industrial and academic) applications of natural fiber composites has been presented in [Shah \(2013\)](#), [Madsen and Gamstedt \(2013\)](#), [Dicker et al. \(2014\)](#) and [Pil et al. \(2016\)](#). An increasing number of scientific studies have looked at various technical applications of biocomposites, from musical instruments ([Phillips and Lessard, 2012](#)) to structural wind turbine blades ([Shah et al., 2013a](#)). Although these studies often articulate the general design specifications the component and material need to satisfy, they seldom demonstrate through a systematic materials selection process that the natural fiber composite materials selected or developed in the study are better than conventional materials and offer specific mechanical, technical, economical, environmental, or ergonomical advantages. While the concept of materials selection is not new, there are only limited studies that have focused on applying materials selection techniques to natural fiber composites or even presenting useful and comprehensive data sets on biocomposites which may be applied during the conceptual design stage.

Conducting a materials selection exercise solely on plant fiber composites (i.e., excluding other materials and polymer composites subgroups), [Sapuan et al. \(2011\)](#) and [Mansor et al. \(2013\)](#) have demonstrated the use of the analytical hierarchy process, a multicriteria

Fig. 2 Ashby plot from illustrating the Young's modulus and tensile strength of traditional engineering materials (top) and natural materials (bottom) on the same axis. Reproduced from Ashby, M., 2008. The CES EduPack Database of Natural and Man-Made Materials (MFA, 20/12/2007). Cambridge: Cambridge University and Granta Design.

decision making method for analyzing and ranking candidate plant fiber composites on the basis of key mechanical and physical properties. They carried out case studies on selecting the optimum plant fiber composites for automotive dashboard panels and brake levers. The same research group has also employed technique for order of preference by similarity to ideal solution, another multicriteria decision making method, to design a concept car bumper beam with hybrid biocomposites material (Davoodi *et al.*, 2011), however the study focuses on optimizing the bumper design for a preselected biocomposite material.

Koronis *et al.* (2013) reviewed green composites (i.e., natural fibers reinforcing a biobased matrix) as adequate materials for automotive applications, and proposed the use of ternary diagrams as materials screening tools. The ternary diagrams consider three weighted bidimensional material properties such as specific stiffness, specific strength and cost per weight, and different materials show up as balloons in different regions of the triangle's area.

Other researchers (Shah, 2013; Ashby, 2008; Dicker *et al.*, 2014; Schuh, 1999; Dittenber and Gangarao, 2012; Sobczak *et al.*, 2012; Carus and Gahle, 2008; Miao and Finn, 2008; Steger, 2010) have looked to produce Ashby-type charts to compare the general mechanical properties of various subclasses of plant fiber composites, against both each other and conventional composites. In particular, the articles by Fortea-Verdejo *et al.* (2017), Sobczak *et al.* (2012), Dicker *et al.* (2014), and Shah (2013, 2014) have been more comprehensive than the others. Fortea-Verdejo *et al.* (2017) illustrate a comparison of the tensile properties of plant fiber composites with glass fiber composites. Sobczak *et al.* (2012) produce detailed mechanical property profiles considering absolute and specific tensile strength and stiffness and Charpy impact strength, for a subgroup of plant fiber composites: Polypropylene composites reinforced with plant and wood fibers. In summarizing major material attributes of plant fiber composites and identifying potential areas of applications, Dicker *et al.* (2014) provide Ashby plots with data on plant fibers (not their composites) amongst other classes of materials such as metals and ceramics. Shah has also compared the performance of silk fiber composites with plant fiber and glass fiber composites in materials selection charts (Shah *et al.*, 2014).

The main objective of this book article is to present Ashby-type materials screening charts on biocomposites to facilitate the product design and development process and consequently aid design engineers in closing the existing gap between current scientific knowledge and actual market applications. Comprehensive mechanical property profiles are presented for both plant fibers and their composites, although focusing on the latter. The Ashby charts will portray (1) absolute tensile properties, (2) tensile properties per unit density, (3) tensile properties per unit cost, and (4) tensile properties per unit eco-impact. The tensile properties of various bast fiber composites are also compared with other classes of engineering materials, and specifically similar glass fiber composites. In addition, other mechanical parameters, specifically fatigue endurance strength, are also employed to produce materials property charts for plant bast fiber composites.

The materials property charts for the plant fiber composites are derived from a large database, which can be found in the appendix of the published articles (Shah, 2013, 2014), to illustrate the effects of different (1) reinforcements forms (short fibers: Pellets and nonwovens; long fibers: Multiaxials and unidirectionals), (2) polymer matrices (thermoplastic and thermosetting), and (3) manufacturing techniques (injection molding, compression molding, hand lay-up, vacuum infusion, resin transfer molding and prepregging). Note that the plant fiber composites included in the database only consider plant bast fibers (e.g., flax, jute, hemp) as reinforcements and nonbiodegradable, petrochemical-derived matrices (e.g., polypropylene, epoxy, polyester). I have previously shown (Shah, 2013) that short-fiber biocomposites show similar mechanical properties for plant fibers from all categories (i.e., bast, leaf, seed, or grass/reed). In addition, only bast fibers [with the exception of cotton (seed) and sisal (leaf)] are commercially available in the form of continuous yarns and textile fabrics that can be used to manufacture aligned composites with significantly improved properties. In addition, the only nonplant based natural fiber with a reasonably wide circulation yarn and fabric form is silkworm silk (ca 250 ktonnes per annum) (Shah *et al.*, 2014). Therefore, bast fibers are ideal to show the typical range in properties of various biocomposites.

With regards to the matrix, most studies and current applications on and of natural fiber composites employ a non-biodegradable or nonbiobased matrix and consequently more data is available for them in literature. Notably, not all biobased matrices are biodegradable and therefore natural fiber composites with biobased matrices may not necessarily be biodegradable. The use of natural fibers as reinforcements in a nonbiodegradable or nonbiobased matrix has been attractive as at least one element (namely, the fiber) is replaced by a renewably sourced material, and such natural fiber composites can be incinerated for energy recovery. While fully green composites are certainly an interesting subset of biocomposites, as biobased thermosets (like furfuryl alcohol and furan resin, and soybean oil based epoxies) typically have inferior mechanical properties to synthetic thermosets, and biobased thermoplastics have comparable mechanical properties to synthetic thermoplastics, the charts produced here can be used for indicative purposes.

Ashby Plots for Plant Fibers

Plant fibers can be categorized according to either the region of the plant they are extracted from, or their utilization upon extraction (Fig. 3). In the former case, plant fibers are classified as bast or stem fibers, leaf fibers, seed fibers, and other fibers (including grasses, reeds, roots, and wood fibers). In the latter case, plant fibers are grouped as primary fibers that are cultivated specifically for their fiber content, and secondary fibers that are waste- or by-products from some other primary utilization. Invariably, fibers from the same category tend to bunch together even in materials property charts (Fig. 4).

In terms of absolute tensile properties [Fig. 4(a)], bast fibers exhibit high strength (up to 700 MPa) and stiffness (up to 70 GPa). Amongst bast fibers, ramie, flax, and hemp have higher properties than jute and kenaf. Leaf fibers tend to have moderate to high strength (300–700 MPa), but much lower stiffness (10–30 GPa) in comparison to bast fibers. Seed fibers, on the other hand, have low to moderate strength (100–500 MPa) and very low stiffness (up to 15 GPa).

Note that the clustering of fibers amongst their respective groups is expected and is due to the distinct chemical composition and structural morphology of fibers from a given group (Shah, 2013), which in turn is a result of evolutionary incentive based on the function of the fiber in the plant. For instance, seed fibers have no structural role in a plant. Consequently, they have low cellulose crystallinity (20%–50%) and high microfibril angles (30–50°) (Shah, 2013) leading to inferior mechanical properties. Bast fibers, on the other hand, exhibit high cellulose crystallinity (50%–90%) and low microfibril angles (2–10°) (Shah, 2013) giving them the structural integrity required to support the plant stem.

Fig. 3 Venn diagram illustrating how plant fibers can be classified based on the part of the plant they are extracted from (i.e., bast, leaf, seed, and other), or their utilization upon extraction (primary, i.e., commercially useful, or secondary, i.e., waste/by-product).

When specific tensile properties of plant fibers are considered [Fig. 4(b)], clustering in their groups of origin is still observed as the density of plant fibers is in the same general range of $1.3\text{--}1.6\text{ g cm}^{-3}$. However, seed fibers, which have a lower density (in the range of $0.7\text{--}1.6\text{ g cm}^{-3}$) due to their low cellulose crystallinity and high luminal porosity (Shah, 2013; Mwaikambo and Ansell, 2001) become slightly more comparable to the leaf fibers. It is interesting to note that while E-glass is not even on the chart (i.e., “in another league”) for absolute tensile properties [Fig. 4(a)], plant fibers appear to be more comparable to E-glass in terms of specific properties [Fig. 4(b)] due to the latter’s higher density of $\sim 2.6\text{ g cm}^{-3}$.

To be viable replacements to synthetic fibers like E-glass, plant fibers not only need to offer better if not comparable specific properties, but also need to do this at a lower if not comparable cost. Considering the tensile properties per unit cost [Fig. 4(c)], it is observed that most of the fibers overlap a strength per unit cost of $650\text{ MPa}/(\text{£kg}^{-1}\text{ g cm}^{-3})$ or a stiffness per unit cost of $32\text{ MPa}/(\text{£kg}^{-1}\text{ g cm}^{-3})$. While some seed and leaf fibers offer high tensile strength per unit cost, bast fibers offer high tensile stiffness per unit cost. Notably, alongside E-glass, pineapple fibers offer a strong combination of strength and stiffness per unit cost. Jute fibers and wood pulp supersede the performance of all the other fibers in terms of property per unit cost. Cotton, on the other hand, is a clear underperformer. It is interesting that despite its low tensile properties per unit cost, cotton fibers were the second largest reinforcing natural fiber in plastics in the European Union in 2010 (Shah, 2013); while 170,000 t of plastics were wood fiber reinforced and 100,000 t of plastics were cotton fiber reinforced, only 45,000 t of plastics were reinforced with other plant fibers with flax, jute, and hemp accounting for 64%, 11%, and 10% of the share (Shah, 2013). It is possible that the availability of the fiber plays an important role in their usage as reinforcements: While the global production of all bast fibers was under 5 million tonnes in 2010, more than 20 million tonnes of cotton was produced in the same year (Shah, 2013).

As plant fibers are from a renewable source, they have acquired an image of being green and requiring low production energies. This is true for most raw plant fibers save cotton due to its high demand of pesticides and fertilizers. As observed in Fig. 4(d), most plant fibers outperform E-glass in terms of tensile properties per unit eco-impact, where embodied energy is taken as the measure for eco-impact. The property chart reveals that the plant fibers group themselves in terms of utilization [Fig. 4(d)]. Primary fibers like flax, jute, and hemp are specifically produced for their fiber content and hence the fibers take up most, if not all, of the environmental burden of growing the plant. Secondary fibers that are waste or by-products from some other primary utilization and therefore do not carry the environmental burden of the primary utilization of the plant. It is expected therefore that primary fibers are heavily penalized in terms of property per unit eco-impact, while secondary fibers receive a boost.

The results in Fig. 4 are generally interesting and show the position of different plant fibers in comparison to one another in terms of mechanical properties that are absolute, specific, per unit cost, and per unit eco-impact. While it could be said that bast fibers offer high absolute and specific properties, and that secondary fibers offer high properties per unit eco-impact, there are underlying complexities that need to be acknowledged. For instance, there are processing limitations with secondary fibers: As these fibers are typically short and there is no established textile industry to produce yarns/rovings and fabrics from them, the manufacture of aligned textile composites for high-performance applications is difficult. Therefore, while raw coir and pineapple fibers may be eco-friendly alternatives to even raw flax and cotton fibers for nonwoven composites for applications in non-structural components such as automotive interior components, the former are not practical options for structural applications. Moreover, the cost and eco-impact of raw plant fibers is considerably different to that of plant fiber rovings/yarns and fabrics (Shah, 2013; Shah et al., 2013a). These need to be incorporated appropriately in the comparison. In essence, in the process of

Fig. 4 Ashby charts comparing the (a) absolute tensile properties, (b) tensile properties per unit density, (c) tensile properties per unit cost, and (d) tensile properties per unit eco-impact, for various categories of plant fibers. Bast fibers are a shade of blue, seed fibers are a shade of green, leaf fibers are a shade of red. Adapted from Shah, D., 2014. Natural fiber composites: Comprehensive Ashby-type materials selection charts. Materials and Design 62, 21–31.

materials selection, property data should be on the actual material form being used (e.g., raw fiber, processed yarn, or textile fabric) and the interpretation of the Ashby charts should be done in combination with information on component processing and fabrication and possibly multiple product specifications.

For comparative purposes, [Fig. 2](#) maps the tensile properties of natural fibers against other natural materials, as well as traditional engineering materials.

Ashby Plots for Plant Fiber Composites

For the construction of materials property charts on natural fiber composites that capture the range of their typical properties, an extensive literature survey was conducted ([Shah, 2013, 2014](#)). While the literature survey focused on biocomposites employing plant bast fibers as reinforcements, properties for a range of (1) reinforcements forms (short fibers: Pellets and nonwovens; long fibers: Multiaxials and unidirectionals), (2) polymer matrices (thermoplastic and thermosetting), and (3) manufacturing techniques (injection molding, compression molding, hand lay-up, vacuum infusion, resin transfer molding (RTM), and prepregging) were incorporated.

[Fig. 5\(a\)](#) presents an Ashby plot for various biocomposites illustrating the range in tensile strength and stiffness. It is noted that that tensile strength and stiffness tend to increase linearly, at an approximate rate of 10 MPa strength to 1 GPa stiffness. More interestingly, it is evident that biocomposites can be categorized into four distinct subgroups with increasing tensile properties in the following order:

- (1) Injection-molded plant fiber composites based on short-fiber pellets whose mechanical properties are low and comparable to the matrix material,
- (2) Plant fiber composites based on nonwoven reinforcements (randomly oriented short fibers),
- (3) Plant fiber composites based on multiaxial textile reinforcements (woven and stitched biaxials, for instance), and
- (4) Unidirectional plant fiber composites.

Therefore, the reinforcement form, in terms of fiber length and orientation, has a governing effect on the properties of the resulting biocomposite due to the substantial difference in length and orientation efficiency factors between the reinforcement forms ([Shah, 2013](#)). The effects of matrix type and manufacturing technique on the properties are comparably smaller but not insignificant as they shift the material properties within that subgroup. In particular, it is found (expectedly) that thermoset-based biocomposites have better mechanical properties than thermoplastic-based biocomposites. The manufacturing technique has a larger effect in the case of unidirectional biocomposites than multiaxial and nonwoven materials. The achievable fiber volume fractions increase and porosity content decrease in the following order: Hand lay-up, vacuum infusion, RTM, compression molding, and prepregging ([Shah, 2013; Harris, 1999](#)). Consequently, the tensile properties of the biocomposites are also observed to increase in the same order.

Despite some dissimilarity in the fiber volume fractions of the plant fiber composite subgroups in [Fig. 5\(a\)](#), in terms of specific properties [[Fig. 5\(b\)](#)] no drastic shifts are observed in their relative positions. This indicates that increasing the fiber volume fraction increases not only absolute but also specific properties. The specific tensile strength and specific stiffness increase fairly linearly, at an approximate rate of 10 MPa/g cm⁻³ specific strength to 1 GPa/g cm⁻³ specific stiffness. Notably, the better absolute and specific properties of aligned and long fiber biocomposites (i.e., multiaxial and unidirectional) indicate that they are more suitable for applications where structural integrity and possibly light weight are the only objectives. [Shah et al. \(2013a\)](#) have previously demonstrated that aligned flax composites are suitable for structural wind turbine blade applications; their flax blade was 10% lighter than a similar construction E-glass blade, with no compromise on mechanical strength.

The Ashby plots in [Fig. 5\(a\)](#) and [\(b\)](#) suggest that unidirectional plant fiber composites, for instance provide 2–20 times better (absolute and specific) tensile properties than nonwoven plant fiber composites and up to 5 times better tensile properties than multiaxial plant fiber composites. However, this does not necessarily imply that unidirectional plant fiber composites would be preferred over the other materials for all applications. Indeed, while reducing cost has long been a critical objective for composites in industrial applications including automotive parts, reducing eco-impact is also becoming an increasingly common target. Subsequently, performance indices incorporating cost and eco-impact may be used to produce a more appropriate materials selection chart for these cases. For simplicity, only the cost and eco-impact (in terms of embodied energy) of the constituent materials, namely the reinforcement and the matrix, have been included in this study. The cost and eco-impact of employing a particular manufacturing process have not been included as these are dependent on various factors such as the part size, production volume, cure process, and labor and direct costs (which are different for different countries). In fact, it is not uncommon for design engineers to use separate selection charts for materials and processes/tools. However, it is notable that with composite materials often the final product (including reinforcement form and matrix type) and the manufacturing process are strongly interdependent.

[Fig. 5\(c\)](#) presents the typical tensile properties per unit cost for the various plant fiber composites. It is worth commenting that in comparison to absolute and specific tensile properties, the spread is much larger for properties per unit cost. Typical thermoplastic matrices such as polypropylene and polyethylene tend to be of lower cost (0.5–2 £/kg) in comparison to thermosetting matrices such as unsaturated polyester, and particularly epoxies and phenolics (1–5 £/kg). Consequently, thermoplastic-based

Fig. 5 Materials selection chart for plant fiber reinforced plastics manufactured with thermoplastic (unfilled balloons) or thermoset (filled balloons) resins, short-random or long-aligned fiber reinforcements, and various manufacturing routes. Charts show (a) absolute properties, (b) specific properties, (c) properties per unit cost, and (d) properties per unit eco-impact. Adapted from Shah, D., 2014. Fig. 6 Ashby plots comparing the (a) absolute and (b) specific Young's modulus and tensile strength of plant fiber composites (filled balloons) with various other engineering materials (unfilled balloons). The inset zoom image in (a) shows materials with properties in a similar range to plant fiber composites. Adapted from Shah, D., 2014. Natural fiber composites: Comprehensive Ashby-type materials selection charts. Materials and Design 62, 21–31, with data on engineering materials from Ashby, M., 2012. CES EduPack. Cambridge: Granta Design Limited.

plant fiber composites perform better in comparison to similar reinforcement thermoset-based plant fiber composites. However, the greater effect (again) is from the reinforcement form, and a trade-off between processing (vis. cost) and fiber orientation (vis. mechanical properties). Nonwoven plant fiber composites outperform unidirectional and multiaxial plant fiber composites in terms of property per unit cost, while injection-molded plant fiber composites are comparable to unidirectional plant fiber composites. Aligned plant fiber reinforcements have additional processing steps and incur substantial costs in converting naturally discontinuous plant fibers, which are readily useable for pellets for injection-molding and nonwoven mats, into yarns/rovings

Fig. 7 Comparison of the absolute and specific tensile properties of plant fiber reinforced plastics with E-glass reinforced plastics. Adapted from Shah, D., 2014. Natural fiber composites: Comprehensive Ashby-type materials selection charts. *Materials and Design* 62, 21–31, with data for glass fiber composites from Ashby, M., 2012. CES EduPack. Cambridge: Granta Design Limited. Sims, G., 2000. 2.05 – Glass fiber reinforced plastics – Properties. In: Kelly, A., Zweben, C., (Eds.) *Comprehensive Composite Materials*. Elsevier, 151–197.

followed by stitched/woven fabrics (Shah *et al.*, 2013a). It is interesting to note that the superior position of nonwoven plant fiber composites justifies their widespread application for nonstructural applications in the cost-driven automotive industry.

When considering properties per unit eco-impact [Fig. 5(d)], the materials selection chart once again reorganizes to a similar form as in Fig. 5(a) and (b) for absolute and specific tensile properties. Unidirectional plant fiber composites offer the highest properties, followed by nonwovens and multiaxial plant fiber composites in a similar range, and then injection-molded plant fiber composites. However, unlike in absolute and specific properties, when considering properties per unit eco-impact, the range of properties for nonwoven plant fiber composites is in the same range as multiaxial plant fiber composites, while the properties of multiaxial plant fiber composites overlaps with unidirectional plant fiber composites. This is due to the lower eco-impact of nonwoven mats in comparison to unidirectional mats and multiaxial fabrics. However, the difference in eco-impact of the reinforcement forms is not as large as observed with cost.

Comparing Plant Fiber Composites With Other Engineering Materials

The materials selection charts generated in Fig. 5 only compare the properties of various plant fiber composites. The database can be used to compare biocomposites with other traditional engineering materials such as wood and other building materials, metals and alloys, ceramics and glasses, and polymers and composites. Fig. 6(a) and b show the relative position of the various PFRPs to some traditional engineering materials, in terms of absolute and specific tensile properties.

It is found that the biocomposites tend to have much lower stiffness and strength than steels and carbon composites [Fig. 6(a)]. Metal alloys of zinc, copper, and aluminum have much higher stiffness, but comparable strength to the biocomposites. The inset zoom image in Fig. 6(a) shows traditional materials with properties in a similar range to biocomposites; these include woods (ply, hard, soft), unreinforced plastics (like poly-amides, epoxies, styrene, urethanes), glass fiber reinforced composites (sheet and bulk molding compounds, and textile composites laminates), and building materials (like brick and concrete).

As plant fiber composites, and polymer composites in general, have low densities, their specific properties are more interesting for comparison [Fig. 6(b)]. In fact, plant fiber composites show comparable specific properties to some metals and their alloys due to the much higher densities of the latter.

Comparing plant fiber composites with glass fiber composites

As E-glass composites dominate the fiber reinforced plastics market, plant fiber composites have often been targeted to replace glass fiber composites (Shah, 2013). Consequently, it would be useful to compare the properties of the various plant fiber composites with similar glass fiber composites.

Fig. 7 presents another format of materials property chart comparing the absolute and specific tensile properties of plant fiber composites with glass fiber composites. Various composite types have been considered based on the matrix type (thermoplastic or thermosetting) and reinforcement form (pellets for injection molding, nonwovens, multiaxials, and unidirectionals). It is revealed that plant fiber composites, particularly unidirectional thermosets and thermoplastics, and nonwoven thermoplastics, perform exceptionally well against similar glass fiber composites in terms of both absolute and specific stiffness. However, both the

Fig. 8 Materials selection chart for plant fiber reinforced plastics based on tensile strength against fatigue strength at 10^6 cycles. Adapted from Shah, D., 2014. Natural fiber composites: Comprehensive Ashby-type materials selection charts. *Materials and Design* 62, 21–31.

absolute and specific tensile strength of plant fiber composites tends to be lower than that of glass fiber composites. Consequently, in terms of tensile properties, it can be said that plant fiber composites may be potential alternatives to glass fiber composites in stiffness-critical applications, but not in strength-critical applications.

Considering Other Mechanical Properties

While tensile properties are commonly used as mechanical parameters for performance indices in material selection charts, depending on the component function and objective other mechanical parameters such as flexural stiffness and strength, impact strength, and fatigue strength may be employed.

As an example, an Ashby plot of ultimate (single-cycle) tensile strength against fatigue strength at 10^6 cycles for plant fiber composites is presented in Fig. 8. The fatigue strength at 10^6 cycles is often used as an endurance limit to design for infinite fatigue life. Note the fewer data points on this chart as fatigue characterization of plant fiber composites is a relatively new area of research. Fig. 8 demonstrates that the fatigue endurance strength of biocomposites is proportional to their tensile strength; this has been suggested by some researchers previously (Shah *et al.*, 2013b; Liang *et al.*, 2014).

Conclusions

As the wide variety of plant fibers offer a range of useful properties, and the versatile nature of composites implies that properties can be tailored by intelligent selection of various composite parameters, plant fiber composites will obviously cover a wide array of properties. Here, comprehensive Ashby-type materials selection charts for plant fiber composites have been produced to facilitate product design and development. The charts are derived from a large database which includes properties for various plant fiber composites based on different (1) reinforcements forms (short fibers: Pellets and nonwovens; long fibers: Multiaxials and unidirectionals), (2) polymer matrices (thermoplastic and thermosetting), and (3) manufacturing techniques (injection molding, compression molding, hand lay-up, vacuum infusion, resin transfer molding and prepregging). The general tensile mechanical property profiles presented will enable the design for (1) optimal stiffness and strength, (2) minimal weight (i.e., optimal specific properties), (3) minimal cost, and (4) minimal eco-impact.

As plant fiber composites are often viewed as alternatives to glass fiber composites, for demonstrative purposes the tensile properties of the various plant fiber composites were compared with similar glass fiber composites. It is foreseen that readers would be able to similarly compare the performance of plant fiber composites with various other materials, particularly natural composites like wood and other conventional polymer composites like aramid and carbon fiber composites.

Highlighting that other mechanical parameters may be critical performance indices for specific products and applications, a materials property chart for a fatigue-limited design was also produced for demonstrative purposes. Similar charts for impact-critical structures, and flexural- or compressive-stress dominated structures, vibration- and damage-tolerant structures would be highly useful.

Introduction

In the year 2005, World Summit on Social Development laid out the key markers for sustainable development goals – economic development, social development and environmental protection (United Nations, 2005). In this key definition, in distinction with earlier viewpoints in economics of development, the most important parameter is to attain them altogether and not neglecting the other. In this regard, sustainable use of resources to drive overall growth of the society without impacting the environment was key to sustainable development. In order to achieve that one of the key drivers of growth is energy. In 2018 the total energy demand of the world amounted to 14046 Mtoe ('Mtoe' means million tons of oil equivalent) with a year over year growth of 2.3%, resulting in 1.7% increase in CO₂ production (Global Energy Statistical Yearbook, 2018). On a broader look this energy demand stems from various sources, starting from HVAC in a building to increase in energy consumption by the microelectronics devices.

According to EIA, in USA 39% of total energy is used by residential and commercial building sector. With regard to building sector, the basic premise of energy efficiency is to decrease energy consumptions, without compromising thermal comfort and indoor air quality in buildings (Asadi et al., 2012). As a result of which, there has been significant amount of research activity in order to improve energy conservation in a building. One of the biggest challenges in this industry is to strike the balance between cost versus performance versus ease of application. Additionally, construction industry also has significant building code restriction, which makes the problem scientifically more challenging.

In the case of microelectronics, the problem with thermal management is even severe. In the year 1965, Gordon E. Moore had predicted that the number of transistors in a dense integrated circuit to be used for computing will double up almost every two years and that prediction is still holding true to keep up with the pace of computing, automation and boom in datacom industry. This has been fueled by change in consumer behavior and scientific advancement. This resulted in an exponential increase in the number of computations per input power (MegaFlops per watt), as high as from 20 MFlops/watt in the year of 2004 to 600 MFlops/watt in 2010 (Garimella et al., 2012). Miniaturization of transistors posed an acute problem in heat dissipation and effective heat removal from microelectronic equipment became one of the biggest challenges as this results in drop in performance, which in turn makes the systems work harder and set the vicious cycle of poor management of resources resulting in ever increasing energy. In order to put things in perspective, according to a recent research report (Shehabi et al., 2016), the total electricity demand for data centers in USA was 4% of national electricity demand. In order to improve the efficiency one of the key aspect is to manage the thermal load properly in order to balance the energy demand sustainably.

All of these clearly show that in order to keep up with the energy demand, the energy production needs to go up. The low hanging fruit is to develop more fossil fuel powered electricity plants but that results in environmental pollution. In order to reduce the environmental impact and to keep up with the energy demand significant amount of energy needs to come from the renewable resources. According to a recent study by British Petroleum, by 2050, one third of world energy needs to come from renewable resources (Mearns, 2014). That is why there has been significant focus on utilizing solar energy to generate power, which can range over different solar collector technologies: (i) photo-voltaic (PV) collector, (ii) solar thermal collector and (iii) photo-voltaic/thermal (PV/T) collector (Ahmed et al., 2017; Khartchenko and Kharchenko, 2014). Whereas a photovoltaic cell's performance decrease with increased temperature, a solar thermal collector requires to store the energy over long period of time to have sustainable supply of heat.

All of these clearly show that there is a definitive need for sustainable thermal management. Nanomaterials provide an interesting approach towards thermal management problem. In this article, we will discuss about three basic nanomaterials for thermal management: (a) thermal interface materials (TIMs), (b) phase change materials (PCMs) and (c) nanofibers for liquid-vapor phase-change heat transfer. These materials broadly classify and describe the overall efforts in the field of nanofiber based sustainable thermal management.

Thermal Interface Materials (TIMs)

As electronic devices with thinner and higher power densities have been developed, thermal load on the device gets higher. The most popular method of managing the heat load is to attach a sink material to the heat producing part, which in most of the cases are the heat producing chipsets. The intent is that the sink draws heat from the chipsets and releases it into another medium (e.g., ambient air, heat transfer fluid etc.). In order to transfer the heat efficiently, the interface between the heat source and the heat sink is extremely critical. The schematic of the heat transfer from the heat source to the heat sink is shown in Fig. 1 (Akbulut and Scholar, 2018). As it is shown in Fig. 1, without TIM, there is always contact resistance between heat source and heat sink owing to

Fig. 1 Schematic of the heat transfer from the heat source to the heat sink, with and without TIM. Reproduced from Akbulut, M., Scholar, E.A., 2018. IEEE Nanotechnol. 12, 19.

the innate surface undulations. Additionally, owing to the phonon or electron scattering process at the interface, the heat transfer across the contact junctions is further reduced (Swartz and Pohl, 1989). To add to that if the contact size is of the order of mean free path of the energy carriers their transport is even further hindered through the quantum confinement effect and changes in phonon/electron dispersion (Pernot *et al.*, 2010). As a result of which, a soft and compliant interface material, called as Thermal Interface Material (TIM), is needed to be applied between heat source and sink, which in essence fills up the undulating structures between heat source and heat sink and thereby reduces the contact resistance. Some of the traditional TIMs are thermal adhesive, thermal grease, thermal filler, phase change materials etc.

The biggest challenge with traditional TIMs are that they lack mechanical strength resulting in additional fixation and/or lack desired thermal conductive properties. As a result of which nanomaterial based TIMs are presently an active area of research. It needs to be mentioned that nanomaterials owing to their smaller size, results in faster response time (t) as $t \sim L^2/\alpha$, where L is the characteristic length of the materials and α is thermal diffusivity. This simple calculation clearly shows that owing to smaller size the characteristic time of response can reduce drastically for nanomaterial based TIMs. As a result of which there has been significant research undertaking of research in the field of TIMs. In development of nanomaterial based TIMs the strategy is to add thermally conductive filler material in a compliant and thermally stable polymeric matrix and use it to capture heat from source and effectively transfer it to heat sink. Along with higher thermal conductivity, another important parameter is co-efficient of thermal expansion (CTE). A high value of CTE can result in poor performance at elevated temperature. It needs to be mentioned that in order to effectively use the nanomaterials to create a material of high thermal conductivity without sacrificing the strength and toughness, nanocomposites with aligned structures are considered to be promising starting materials (Liang *et al.*, 2011; Xie *et al.*, 2005; Chen *et al.*, 2017). In order to achieve that, nanocomposites comprising of aligned 1D CNTs were prepared, which showed efficient heat dissipation and reduced interfacial thermal resistance, yielding excellent through-plane TCs ($KL = 0.46\text{--}4.87 \text{ W/m K}$) (Marconnet *et al.*, 2011; Borca-Tasciuc *et al.*, 2007; Huang *et al.*, 2005). Similar to CNTs, boron nitride nanotubes (BNNTs) were also used to make high thermal conductivity composite materials. It needs to be mentioned that BNNTs has similar structure like CNTs resulting in high thermal conductivity but very low electrical conductivity making it one of the ideal candidates as TIMs. It was shown that it is possible to obtain 20-fold thermal conductivity improvement in BNNT-PMMA polymeric composite, while holding excellent electrical insulating properties (Zhi *et al.*, 2009). However, the challenge with

tubular filler to produce TIMs with high thermal conductivity is that it is extremely difficult to mix higher amount of filler owing to high aspect ratio of the filler. Additionally, the method of producing these tubular structure is extremely expensive. As a result of which significant focus has been provided to produce TIMs with 2D nanofillers, namely-graphene, hexagonal boron nitride (hBN), transition metal dichalcogenides (TMDCs), and black phosphorous etc. (Akbulut and Scholar, 2018; Renteria *et al.*, 2014; Saadah *et al.*, 2017; Shtein *et al.*, 2015; Weng *et al.*, 2016; Bao *et al.*, 2016; Jo *et al.*, 2013; Liu *et al.*, 2017; Zhang *et al.*, 2017; Zha *et al.*, 2016; Lee *et al.*, 2015). In the following two paragraphs, we will talk in detail about graphene and hBN nanosheets based TIM.

Pristine graphene is a zero-bandgap material, whereas hBN has a bandgap of 5.9 eV, which means that while graphene is electrically conductive, hBN is electrically insulating. Additionally, hBN is thermally more stable in comparison to graphene as graphene in presence of oxygen oxidizes to graphene oxide (GO) at 450°C hBN shows no sign of oxidation temperatures below 850°C (Akbulut and Scholar, 2018). Individual graphene nanosheets is $\sim 1500\text{--}2500$ W/m K (Faugeras *et al.*, 2010) whereas its out-of-plane thermal conductivity ~ 6 W/m K (Balandin, 2011). However, thermal conductivity increases with the logarithm of graphene length, L , plateauing around a length of 8–9 μm (Akbulut and Scholar, 2018). hBN nanosheets have very high in-plane thermal conductivity ($\sim 600\text{--}1000$ W/m K) but very poor out-of-plane thermal conductivity (~ 2 W/m K) (Ma and Sun, 2017). However, as the thickness increases the overall thermal conductivity of hBN nanosheets reaches its bulk value. Another important thing is that the CTE of graphene and hBN are $8 \times 10^{-6} \text{ K}^{-1}$ and $7.2 \times 10^{-6} \text{ K}^{-1}$, which almost as the same order as silicon, gallium arsenide, copper and aluminum making both of these two materials very attractive material for electronics application (White, 1973).

Significant work has been done to produce graphene and hBN based TIMs. Some of the most popular methods are vacuum-assisted filtration (Liang *et al.*, 2011; Li *et al.*, 2014), layer-by-layer (LBL) assembly (Song *et al.*, 2017), magnetic and electrical fields (Lim *et al.*, 2013); freeze casting (Yang *et al.*, 2017; Zhao *et al.*, 2017), solvent evaporation techniques (Kumar *et al.*, 2016). Zeng *et al.* (2018) in their work created large-area bulk oxidized cellulose nanocrystal (OCNC)/graphene nanocomposites with highly oriented structures using a large scale evaporation induced self-assembly process followed by thermal curing. They showed that this process resulted in well aligned nano-sized graphene layers. This resulted in highly interconnected and continuous thermal transport parallel to the alignment resulting in excellent in-plane thermal conductivity of 25.66 W/m K and a thermal conductivity enhancement (η) of 7235% with only a 4.1 vol% graphene loading. They also showed how their well aligned graphene layer resulted in extremely well dissipation heat in comparison to randomly oriented graphene layers (Fig. 2(a)). Chen *et al.* (2019) produced PVDF and hBN based nanofiber mat by electrospinning, which showed significant flexibility without even at a very high loading of hBN nanosheets. The resulting structure had an in-plane thermal conductivity of 16.3 W/m K at a thickness of 18 μm . They have also used it with MOFSET as a TIM and showed its efficacy (Fig. 2(b)).

Phase Change Materials (PCMs)

PCMs are one of the most ubiquitous families of materials used in our daily lives. PCMs are used as thermal energy storage (TES) materials. As the name suggests, these materials use the phase change process of the material to store energy, in the latent form. During the phase change process of turning from solid to liquid, their temperature remains constant, while the material consumes energy. Below and above the temperature range at which the phase change occurs, heat is stored as sensible heat but the temperature of the material increases. In the case of PCMs, these materials change from solid to liquid when heated, thus absorbing energy in the endothermic process. When the ambient temperature drops, the liquid PCMs will turn into solid state materials again while releasing the earlier absorbed heat in an exothermic process. The use of PCMs date back to almost 500 BCE, when Greeks and Romans used mutton fat (tallow) to make candles. In China during Qin dynasty (almost 200 BCE), whale fat was used to make candles. These candles are perfect example of PCMs. Owing to the innate capability of PCMs to store energy, they are considered to be one of the key components of TES medium. Their applications range from construction practice to renewable energy storage to maintaining thermal equilibrium of electronics chipset (Amaral *et al.*, 2017; Raam Dheep and Sreekumar, 2014; Wan *et al.*, 2016). PCMs can be broadly classified into three categories – inorganic, organic and eutectic mixtures (Amaral *et al.*, 2017). Some of the advantages and disadvantages of these PCMs are shown in Table 1 (Amaral *et al.*, 2017; Ahmed *et al.*, 2017). However, although the inorganic PCMs are quite attractive from the viewpoint of price but their high temperature of operation, corrosive nature, toxicity etc., limits their applications to some specific uses, e.g., thermal energy storage for solar applications (Ahmed *et al.*, 2017). Whereas, organic PCMs, namely-paraffin wax, has been used over a wide range of applications (Amaral *et al.*, 2017; Raam Dheep and Sreekumar, 2014; Wan *et al.*, 2016). However, irrespective of the PCMs, the biggest drawback for PCMs are that their thermal diffusivities are intrinsically low. This results in poor thermal response. In order to avoid that two possible techniques can be employed: (a) addition of high thermally conductive filler to increase effective thermal diffusivity, (b) encapsulate PCMs in nanotubular structures and thereby reducing the characteristic time of response. In the next two paragraphs a brief overview of both of these two methods will be described.

PCMs Incorporated With Conductive Nano-Filler

In order to achieve higher thermal conductivity aka effective higher thermal diffusivity, one of the most intuitive and well researched area is the incorporation of highly conductive nano-filler (e.g., CNTs, graphene, metal and ceramic nanoparticles etc.).

Fig. 2 (a) Schematic of the thermal test setup, finite-element analysis of surface temperature variations with time and demonstration of thermal transport properties of oxidized cellulose nanocrystal (OCNC)/graphene nanocomposites with randomly dispersed graphene sheets and highly oriented graphene sheets are shown. (b) Upper left corner of the panel shows the optical photograph of the MOSFETs integrated with thermal interface materials prepared from electrospun PVDF and hBN nanosheets, whereas lower left corner shows schematic diagram of a MOSFET integrated with a thermal interface material. Upper right hand corner shows the infrared thermal images of MOSFETs integrated with different thermal interface materials and lower right hand corner shows the surface temperature variations of MOSFETs versus time. Reproduced from (a) Zeng, H., Wu, J., Ma, Y., *et al.*, 2018. *ACS Appl. Mater. Interfaces* 10, 41690. (b) Chen, J., Huang, X., Sun, B., Jiang, P., 2019. *ACS Nano* 13, 337.

Table 1 Different types of PCMs and their relative advantages and disadvantages

Type of material	Advantages	Disadvantages
Organic (e.g., Paraffin wax)	● Non corrosive ● Low or no supercooling effects ● Chemical and thermal stability ● Good thermal behavior ● Adjustable transition zone ● Availability in a large temperature range ● No segregation ● Good nucleation rate ● No dangerous (chemically) ● Recyclable ● Compatible with wide range of materials	● Low phase change enthalpy ● Low thermal conductivity, density and melting point ● Flammability ● Highly volatile ● Volume change during phase change ● Expensive
Inorganic (e.g., Hydrated salts)	● Great phase change enthalpy ● High energy storage density and thermal conductivity ● Not flammable ● Less expensive (Low cost) comparative to the organic ● Low volume change ● Sharp phase-change	● Supercooling effect ● Corrosive ● Decomposition and phase separation ● Phase segregation and lack of thermal stability ● Lower compatibility with other materials ● Slightly toxic ● Incongruent melting and dehydration in the process of thermal cycling ● Poor nucleating properties
Eutectic mixtures (e.g., Mixture of different PCMs)	● Sharp melting temperature ● Volumetric thermal storage density slightly above organic compounds ● No segregation and congruent phase-change	● Limited data are available on their thermophysical properties ● Quite strong odor

Note: Amaral, C., Vicente, R., Marques, P.A.A.P., Barros-Timmons, A., 2017. *Renew. Sustain. Energy Rev.* 79, 1212. Ahmed, S.F., Khalid, M., Rashmi, W., Chan, A., Shahbaz, K., 2017. *Renew. Sustain. Energy Rev.* 67, 450.

The reasons for addition of nanofiller are that: (a) the mixing is relatively straight forward, (ii) with relatively lower loading, it is possible to get higher thermal conductivity owing to improved percolation of nano-fillers. Parameshwaran *et al.* (2013) incorporated silver nanoparticles to organic ester. investigated the performance of organic ester by incorporating silver nanoparticles, where they were able to reduce latent heat capacities by 7.88% in freezing and 8.91% in melting whereas thermal conductivity of composite PCMs increased by 10%–67% more compared to base PCM and thereby increasing effective thermal diffusivity. Wang *et al.* (2010) showed that by adding copper nanoparticle to paraffin wax they were able to change thermal properties significantly. In this work they added various amount of copper nanoparticle (0.1, 0.5, 1.2 wt%). It was found that the latent heat changed significantly. Li *et al.* (2013) prepared MWCNT based nanocomposite with stearic acid as the PCM and found that addition of MWCNT improves the thermal conductivity and also increases the discharging rate to about 91% and lowers the charging rate to 50% of stearic acid, when the volume fraction of the additive is 5%. Sari and Karaipekli (2007) investigated the effect of addition of expanded graphite in paraffin and found that by increasing amount of expanded graphite the thermal conductivity can be increased by almost 4 times. Several studies were performed for the focus work of EU DISTOR (Energy Storage for Direct Steam), where the intent was to build better steam accumulator for solar thermal power plant, where both lab-scale and industrial application of graphite- $\text{NaNO}_3/\text{KNO}_3$ were studied in detail (Tamme *et al.*, 2008; Steinmann and Tamme, 2008; Pincemin *et al.*, 2008; Acem and Lopez, 2010). They found that they were able to increase the thermal conductivity between 10 and 31 times depending on the graphite particle size, working temperature and elaboration time (dispersion, infiltration and cold compression). Liu *et al.* (2018) created graphene aerogel embedded with alkane, alcohol and carboxylic acid PCMs using hydrothermal synthesis. They found that resultant composite structure comprising of rGO/PCM has a significantly enhanced thermal conductivity of $3.21 \text{ Wm}^{-1} \text{ K}^{-1}$ with the rGO loading of 10 wt%. They also replaces part of graphene with silver nanoparticles and found that the thermal conductivity of rGO/PCM/Ag could be as high as $5.89 \text{ Wm}^{-1} \text{ K}^{-1}$.

Nanoencapsulated Phase Change Materials

Nanoencapsulation or nanoconfinement of PCMs allow us to reduce the length scale drastically and thereby improve the characteristic time of response. Apart from improving thermo-physical properties, confinement also improves upon other drawbacks of PCMs. As an example- for inorganic PCMs one of the biggest challenges is the loss of crystallization water during phase transition and supercooling. Encapsulation at nanoscale help prevent such issues. There has been significant amount of work in literature regarding nanoencapsulation of PCMs. A very good review of the techniques of nanoencapsulation can be found in Aftab *et al.* (2018). One of the popular method is to encapsulate PCM in polymer capsule in situ, which can be achieved via emulsion polymerization (Huang *et al.*, 2017; Shirin-Abadi *et al.*, 2011), in-situ polymerization (Fang *et al.*, 2013, 2008). Similar to nanoencapsulation in a polymer

shell via polymerization, sol-gel methods were also used to encapsulate PCMs in inorganic shell (Zhu *et al.*, 2015). Apart from in situ encapsulation, PCMs were also encapsulated in the core of electrospun nanofiber (Sirohi *et al.*, 2015; Semnani Rahbar *et al.*, 2016). PCMs were also encapsulated in mesoporous silica particles (Mitran *et al.*, 2018; Zhang *et al.*, 2010; Lai *et al.*, 2016).

One of the most interesting and easily scalable process was proposed by Sinha-Ray *et al.* (2011a). In this work, the wax was encapsulated inside CNTs via self-sustained diffusion (Bazilevsky *et al.*, 2007, 2008). CNTs were added to solution of wax and sonicated for 30 min resulting in homogeneous suspensions. After that the vial cap was kept open in a chemical hood until complete evaporation of benzene. During this process the self-sustained diffusion of solutes into CNTs took place. Then, benzene was added to the deposit and sonicated for 3–4 min to rinse any solute which possibly could have been deposited outside the CNTs. A representative TEM image is shown in Fig. 3(a). It was also found that owing to nanoencapsulation, apart from reduction of characteristic time of response, the temperature range of operation widened (as shown in Fig. 3(b)). Following this work, CNTs intercalated with erythritol and wax was prepared (Sinha-Ray *et al.*, 2014a), which was used to create coolant suspension to cool microchannels, where for intercalated wax sample aqueous and intercalated erythritol oil based suspension was prepared (Fig. 3(c)). Special care was taken to create surfactant stabilized aqueous suspensions of 1 wt% CNTs, which did not clog a 603 μm channel, whereas in a 1803 μm channel flows of suspensions of up to 3 wt% wax-intercalated CNTs were found to be possible. The flow rates of such suspensions were in the range 5–55 ml min^{-1} . It was found that the presence of the surfactant NaDDBS in water led to an apparent slip at the channel walls, which enhanced the convective heat removal from a hot copper block, in which the microchannels with flowing aqueous coolant were embedded. The presence of wax inside CNTs additionally facilitated heat removal through the latent heat of wax fusion. Wax melted in the range 45–47°C and this effect alone was responsible for the maximum temperature reduction of 1.9°C (Fig. 3(d)). The erythritol melted in the range 118–120°C and this effect alone was responsible for the maximum temperature reduction of 3.2°C in flows of the oil-based 1.5 wt% suspension of erythritol-intercalated CNTs (Fig. 3(e)). The present approach showed possibility in the case of mixtures of different PCMs, e.g., wax and erythritol (separately in different CNTs, or together in the same CNTs) to widen the temperature range in some applications.

Nanofibers for Liquid-Vapor Phase-Change Heat Transfer

As the energy and cooling demand for microelectronics increases, there has been significant emphasis on cooling technique with enhanced heat removal capacity. Liquid-vapor phase-change processes, such as boiling, evaporation, and condensation, is the most efficient and widely exploited for thermal management of high-power systems to maintain adequate performance and to ensure system reliability and safety (Wen *et al.*, 2018a,b; Amir, 2012; Boreyko and Chen, 2013). There has been significant amount of work that has been done by nanotexturing the surface (Wen *et al.*, 2018a,b). The basic premise of all these works has been to increase the hydrophilicity of the surface. However, most of these processes are extremely expensive and thereby lacks the practical or large scale application that can be employed from device level to large scale applications. However, recent progress in polymer nanofibers via electrospinning, solution blowing and electricity assisted solution seems to have the answer to this problem. For readers unfamiliar with these processes are highly encouraged to read the following references to get a brief overview of the process (Sinha-Ray, 2018). In this section, we will limit our discussions to nanofiber mediated heat transfer via liquid-vapor phase change process. Two different modes of heat transfer methods will be discussed: (a) drop impact method and (b) pool boiling method.

Drop Impact Method

Drop impact method (spray on demand) of cooling a hot surface is extremely well known. Applications can range from UAVs, space shuttles, data centers to autonomous vehicles etc. However, the challenge is that as the temperature of the hot surface nears the boiling point of the coolant, the coolant bounces off the surface because as the drop touches the surface, immediately a vapor pillow forms underneath the drop resulting in levitation of the drop. This effect is called “Leidenfrost Effect” (Fig. 4(a)). As a result of the Leidenfrost effect the water droplet bounces around the surface without getting fully utilized. In fact, we all have seen this effect in our everyday life. In kitchen, if we put drop of water on a hot skillet, the water bounces around. In order to quickly cool the skillet, we hold hot skillet under running faucet and inherently use a lot more coolant (water). For a kitchen type application, such usage is OK but when we think about mission critical and space crunched situations like UAVs, space shuttles, autonomous vehicles etc., neither we have the luxury nor we have the resources to use such a huge amount of coolant. So, the most important way to improve the efficiency of cooling under drop impact is to do away with the Leidenfrost effect and electrospun fibers seem to have the capability to do so efficiently.

Fig. 3 (a) TEM image of a wax intercalated CNT is shown. (b) DSC thermogram of wax intercalated CNT is shown. (c) Schematic of the experimental setup employed to study heat removal using microchannel flows of wax-intercalated CNTs is shown. (d) and (e) show the temperature evolution in a microchannel flow for wax and erythritol suspension respectively. Black symbols correspond to pure water, red symbols to the aqueous surfactant solution, green symbols to the aqueous suspension of the empty CNTs, and blue symbols to the suspension of the PCM-intercalated CNTs. Lembach *et al.* (2010) came up with an elegant yet powerful solution to eliminating Leidenfrost effect. They first theoretically showed that if a coolant droplet of diameter a hits a porous surface with pore diameter $\sim D$ at a velocity of U , the velocity of penetration inside the porous surface (V) $\sim Ua/D$. This shows that by increasing a/D ratio, we can increase V . Electrospun nanofiber mat has a pore size $\sim 10\text{--}40\text{ }\mu\text{m}$. If the coolant droplet has a diameter $\sim 1\text{ mm}$, with $U \sim 1\text{ m/s}$, V can be extremely large. Additionally, the pores in electrospun fibers are interconnected. As a result of which, once the coolant enters the electrospun mat, it gets pinned. Based on this theoretical knowledge, it was shown that surface coated with polymer nanofiber mat can do away with Leidenfrost effect (Lembach *et al.*, 2010; Weickgenannt *et al.*, 2011). However, one of the biggest challenges with polymer nanofibers in thermal management application is that owing to the low thermal diffusivity of the polymer nanofibers, the heat transfer capability of hot surface coated with polymer nanofiber under drop impact can suffer. As a result of which, it is extremely important to have a high thermal diffusivity nanofiber mat coating. In order to alleviate the problem, a simple yet powerful method of preparing metallized nanofiber mats were shown (Sinha-Ray *et al.*, 2011b). First of all the nanofiber mat deposited on the copper surface was sputter coated. Then the sputter coated nanofiber mats were electroplated using simple electroplating bath. Metallized nanofiber mats with different metals (copper, nickel, silver and gold) were prepared. SEM image of electroplated copper nanofiber is shown in Fig. 4(b) and (c). First of all it was found that all the metallized nanofiber mats were able to do away with Leidenfrost effect as shown in Fig. 4(d), where it can be seen that water droplet keeps bouncing around with evolution of time, whereas the water droplet gets pinned on the metallized nanofiber mat coated copper substrate. It was shown that out of all the metallized nanofiber mats, copper nanofiber performed the best from the viewpoint of structural integrity and heat transfer efficiency. It was found that the copper nanofiber is capable of removing almost 1 kW/cm^2 of heat flux. This work was extended to find the efficiency of the copper nanofiber mat under continuous drop impact using a drop-on-demand generator under different gravity condition (0 g, 1 g and 1.8 g) and it was found that in all of these cases the coating was able to remove high heat flux in comparison to the bare surface and do away with Leidenfrost effect (Sinha-Ray *et al.*, 2014a,b).

Pool Boiling Method

Pool boiling is known as a very effective mechanism of liquid vapor phase change heat transfer due to its high heat flux values. The regimes of pool boiling can be divided on the boiling curve as free convection boiling, nucleate boiling, transition boiling, and film boiling (Nukiyama, 1966). Among them nucleate boiling is considered to be the most desirable heat transfer regime, since it is

Fig. 5 Comparison of pool boiling data for bare copper and metallized nanofiber coated surface is shown. Panel (a) and (b) shows evolution of heat flux and BHT vs. wall superheat for ethanol as boiling medium respectively. Panel (c) and (d) shows evolution of heat flux and BHT vs. wall superheat for water as boiling medium respectively. Reproduced from Jun, S., Sinha-Ray, S., Yarin, A.L., 2013. *Int. J. Heat Mass Transf.* 62, 99.

associated with high heat fluxes at low superheat surface temperature, which is attractive for such practical applications as cooling of electronics, boilers, nuclear and chemical reactors and refrigeration systems. However, there exists a critical value of heat flux called critical heat flux (CHF) at which nucleate boiling transforms into film boiling. The latter involves heat transfer through coolant vapor rather than through liquid coolant itself, which is a weak heat transfer mechanism. There were multiple efforts to increase CHF and boiling heat transfer coefficient (BHT), which is by definition the heat flux divided by the corresponding superheat temperature. In particular, boiling on roughened surfaces was investigated (Webb and Kim, 2005). It was found that roughened surfaces increase BHT coefficient, which stems from an increased area density of nucleation sites. Microporous coatings to enhance pool boiling were studied in Song *et al.* (2018), Li and Peterson (2010), Rainey and You, (2000). In particular, the authors of Li and Peterson (2010) sintered microporous surfaces and found that CHF on them strongly depends on the coating thickness, volumetric porosity and pore size. They attributed the improvement of heat transfer in their experiments to an increased effective heat transfer area. It was also found in Li and Peterson (2010) that when the coating thickness reaches approximately 2 mm, CHF reaches maximum, which was twice that corresponding to bare surface. Volumetric porosity does not affect much CHF value. On the other hand, CHF increases with increasing the pore size upto 250 μm (Li and Peterson, 2010). The effect of nanoparticles suspended in liquid on pool boiling was studied in Jothi Prakash and Prasanth (2018), You *et al.* (2003), Kim *et al.* (2007), Kim and Kim (2009). The authors (You *et al.*, 2003) reported that CHF can be doubled due to the presence of nanoparticles. An enhancement of CHF in nucleate boiling in presence of nanoparticles is commonly attributed to an increase surface in wettability and surface roughness and some other factors (Kim *et al.*, 2007; Kim and Kim, 2009). However, in Kim *et al.* (2007) the BHT coefficient decreased due to (i) a build up of nanoparticle layer, which reduces heat transfer from the metal surfaces in pool boiling and (ii) a reduction of nucleation site density caused by a decrease in the contact angle. Pool boiling on a surface coated by nanofiber mat seems to do away with the problems and improve heat transfer efficiency BHT coefficient and enhance CHF.

One of the first work in this direction was done by Jun *et al.* (2013). In this work, the authors used metallized nanofiber mat coated mat based on the techniques developed earlier (Sinha-Ray *et al.*, 2011a,b). In this work, it was shown that nanotextured copper surfaces coated with copper nanofiber mats possess a 6–8-times higher heat flux and heat transfer coefficient in nucleate boiling of ethanol in comparison with those of the corresponding bare copper surface (Fig. 5(a–b)). For the nucleate boiling of water, the heat flux and heat transfer coefficient of nanotextured surfaces is 3–5 times higher than those of the bare copper surface (Fig. 5(c–d)). The reason was also explained theoretically. The theory attributed the superiority of nanotextured surfaces in comparison to the corresponding bare surfaces to the fact that the effective liquid temperature in liquid in the vicinity of such fluffy surfaces is higher than near the smooth surfaces. In the theoretical work, it was shown that because of the fluffiness, the average

Fig. 6 (a) Pool boiling of ethanol on metallized supersonically solution blown nanofiber is shown for two different experiments. (b) Comparison of pool boiling of ethanol water mixture (3:1) on bare surface with metallized supersonically solution blown nanofiber is shown, where the same surface was used twice to do the experiments and the filled and open structure shows pool boiling done on same surface at two different times. (c) High speed images of pool boiling of Novec 7300 on bare surface, electrospun nanofiber coated surface and supersonically solution blown nanofiber coated surface are shown. It can be visibly seen that supersonically nanofiber coated surface creates the smallest sized bubble. Reproduced from (a–b) Sahu, R.P., Sinha-Ray, S., Sinha-Ray, S., Yarin, A.L., 2015. *Int. J. Heat Mass Transf.* 87, 521. (c) Sinha-Ray, S., Zhang, W., Sahu, R.P., Sinha-Ray, S., Yarin, A.L., 2017. *Int. J. Heat Mass Transf.* 106, 482.

temperature the boiling fluids feel near the surface is significantly higher than that of bare surface resulting in higher heat flux removal rate.

However, one of the big challenges of this work was that the electrospun nanofiber mats were delaminating making them difficult to use for long term application. To mitigate that supersonically solution blown nanofiber followed by copper plating was used (Sahu *et al.*, 2015, 2016). Firstly pool boiling of ethanol, water and their binary mixtures were studied for bare copper and nano-textured surfaces formed by supersonically solution-blown, copper-plated nanofibers (Sahu *et al.*, 2015). It was found that boiling curves measured on nanotextured surfaces revealed heat fluxes 2–7 times higher than those on the bare surfaces with the same surface superheat within the range of the heat flux supplied in the present work. Moreover, in several cases, such as pure ethanol and ethanol–water mixture (3:1), a hysteresis of the boiling curve was observed in pool boiling on nano-textured surfaces. Namely, as the heat flux at the surface was increasing, the surface superheat reached a maximum of 7.2°C and then started to decrease resulting in a backward turn of the boiling curve (Fig. 6(a–b)). The long pool boiling experiments of duration of 5–6 h, also repeated twice on the same nano-textured surface, showed that the surfaces did not delaminate from the underlying copper substrate or deteriorate, in distinction from the Jun *et al.* (2013). The surface was also used to study pool boiling of Novec FC 7300 fluid, pure water and self rewetting water–heptanol mixture (Sahu *et al.*, 2016). The heat flux (the heat removal rate) and the corresponding heat transfer coefficient were found to be higher on the copper-plated nanofiber surface. The pool boiling data for the self-rewetting fluid revealed a higher heat removal rate from the nano-textured surfaces than even the one for pure water. In all these works, copper plating was used, which may not be possible for lot of practical applications. As supersonically blown nanofibers are intrinsically extremely small in diameter in comparison to electrospun nanofiber, the characteristic time of response is fast and adheres strongly with the surface. Based on this logic, Sinha-Ray *et al.* (2017), used supersonically blown nanofiber to nanotexture the surface and studied the pool boiling characteristic of Novec 7300 and water. It was found that the supersonically-blown polymer nanofibers significantly enhanced the heat removal rate from the heater surface, especially in the case of Novec 7300 fluid where the maximum surface superheat was reduced by at least 7°C versus 5°C for the electrospun surface. The supersonically blown polymer nanofibers (diameter ~100 nm) facilitated bubble nucleation serving as active nucleation sites. Such nanofiber mats also possess a larger number of small pores than electrospun nanofibers, which cut and release the growing bubbles. Supersonically-blown nanofibers revealed the best adhesion to the copper substrate and retained their architecture after prolonged 7.5 h of boiling. The experiments conducted with DI water did not show as strong enhancement of the heat removal rate, as the experiments with Novec 7300 fluid did, even though compared to the bare copper surface, the surface superheat was

reduced on supersonically blown nanofibers by 1.7°C at the maximum heat flux after 8 h of boiling. Novec 7300 is a low surface tension fluid and the onset of heterogeneous nucleate boiling takes place at a lower surface temperature compared to DI water. Accordingly, in Novec 7300 fluid the size of vapor bubbles is smaller and thus affected by the nanotexture of the heater surface (Fig. 6(c)). DI water, on the other hand, possesses a high surface tension, and thus the onset of boiling takes place at a higher surface temperature. The larger bubbles in DI water are insignificantly affected by the surface nano-texture, and accordingly, the enhancement of heat removal is diminished in DI water compared to Novec 7300 fluid. It was also found that after boiling in DI water, electrospun nanofibers were completely delaminated from the copper substrate, unlike the supersonically-blown nanofibers which retained their adhesion and architecture.

Conclusion

Development in a society can be described almost like a double-edged sword. On one hand without growth, development is difficult to attain, whereas on the other hand the resources required to sustain growth results in depletion faster than the rate of replenishment resulting in unsustainable development. In this regard, ecological economist Herman Daly once asked, “what use is a sawmill without a forest?” Power is the key to our society’s development. In order to develop sustainably, there are dire needs for efficient utilization of available energy, which necessitates efficient thermal management across different applications. Nanomaterials for thermal management is an exciting area of research. While the development continues, the biggest challenge for efficient utilization of nanomaterials for thermal management is the price competitiveness. While microelectronics can afford the cost of nanomaterial based thermal management system, it can be hard for mass market application (e.g., construction industry, solar cell etc.) to handle the cost. In that regard, the researchers need to develop systems that are more cost effective. At the same time, as nanomaterial based thermal management system hold key to a lot of issues with efficient thermal management system. So, the policymakers also need to think of policies (e.g., incentives) to bring the technologies to fruition.

Introduction

Due to the limited natural resources, scientists are seeking new material that can replace heavy and expensive materials needed in product manufacturing. Based on this concept composite idea was originated and now composites have become a major research topic due to their versatile properties, applications as well as economic utilization of resources. The metallic materials have their own properties, whereas the composite properties are customizable according to the desire of customers through a specific fiber, fiber orientation, fiber volume and fiber modification. Due to this tailoring property, the interest on composite is highly increasing in automobile, aerospace, underwater and household accessories from small component to large component.

In composite, there are two components, namely fiber (reinforcing material) and matrix. The matrix material can be polymer, ceramics and metal. Depending on the end use, matrix materials are selected during composite fabrication. Depending on the available fiber form, reinforced materials are used in the composite. In the composite fiber can be in the form of particles, fiber as well as sheet or fabric. There are several methods to fabricate the polymer matrix composites. Compared to other popular methods, extrusion compounding and injection molding processes are commonly employed to fabricate polymer composites (Maity *et al.*, 2007). Thereafter, prepared composite are tested and the results are analyzed. If the obtained results are according to the desired expectation, the technology is transferred to the industries for manufacturing otherwise; again fiber modification is done so that they can be more widely used as shown in Fig. 1.

On the other hand, fiber can be natural and synthetic or man-made. However, in bio-composite, biodegradable natural fiber is used as reinforcing material and synthetic fiber is used as reinforcing material in case of the synthetic fiber composite. Matrix can be polymer (polyester, polypropylene, epoxy, polyethylene, polyvinyl chloride and so on), metal and ceramics. As natural fiber grows naturally, there is non-homogeneity in their property, whereas synthetic fibers are man-made whose properties are not varied widely. Important physico-mechanical properties of selected synthetic and natural fibers are listed in Table 1.

From Table 1, it is clear that the range of tensile properties for synthetic fibers is higher compared to natural fibers. Synthetic fiber such as glass, Kevlar also has different categories. These categories such as kevlar (29, 49, 100, 119, 129, 149, 981), carbon (type I and type II) and glass (A, C, D, E, R, S, ECR) are based on their properties. The tensile strength of glass fiber varies between 2900 and 3620 MPa. The maximum and the minimum value of tensile strength for glass fiber are listed as a range in Table 1. Similarly, in this article, the range for a criterion of an alternative presents the maximum and minimum value of respected criteria for a respected alternative. From Table 1, it is perceived that boron fibers are denser as compared to other fibers, however natural fibers are lighter indeed as well as perishable. Usually stronger and stiffer fiber is used in the composite to improve the performance. To obtain better performance for a particular application appropriate fiber and matrix selection is required.

In case of fiber selection for a composite, researcher or any industry first seeks for local fiber. For example, a scientist or entrepreneur of industry in Bangladesh will first try through jute, rice husk, banana, bamboo, and coir as they are easily available regarding bio-composite. On the other hand, sisal and abaca fibers are not available in this region. Thus, they try to will ignore these types of fibers during composite design. Furthermore, the matrix selection also depends on the matrix availability in the local market as well as price. However, matrix selection mainly depends on the final use that is composite properties, available fabrication methods, cost of labor and environmental consciousness. Some of the important criteria of commonly used selected polymer matrix material (for example thermosetting, thermoplastic and bio-degradable) are listed in Table 2. The polymer matrix material can be in the form of granule, palate, along with the liquid. Thermoplastic matrix polypropylenes (PP), low density polyethylene (LDPE) are available as granule and sheet whereas bio-degradable polylactic acid (PLA) is available as liquid and thin

Fig. 1 Flow diagram of fiber reinforced composite development.

Table 1 Physico-mechanical properties of natural and synthetic fiber

	Fiber	Density (gm/cc)	Tensile strength (MPa)	Young's modulus (GPa)	References
Synthetic fiber	Aramid	1.40	300	124	(Pandita <i>et al.</i> , 2013)
	Kevlar (29)	1.30–1.44	2900–3620	70–83	(Yan <i>et al.</i> , 2014)
	Nylon	1.14	54	0.94–3	(Yan <i>et al.</i> , 2014)
	Glass (E)	2.50	2000–3000	70	(Célino <i>et al.</i> , 2014)

sheet. In addition, a thermosetting polymer such as polyester is available as fiber and liquid whereas epoxy is available as liquid only. From [Table 2](#), it is clear that the Young's modulus is lower for a thermoplastic matrix, whereas it is higher in case of thermosetting matrix materials.

Thermoset polymers are good for long fiber composite fabrication and from [Table 2](#), it can be concluded that thermoset polymers have high density (1.1–1.5 gm/cc), high tensile strength (20–73 MPa) and Young's modulus (3.3–5.0 GPa) as compared to thermoplastic and bio-degradable matrix materials. However, they need long curing time and difficult to recycle. On the other hand, thermoplastic polymers need short production time, are able to recycle and can be reused as well as good for short and discontinuous fiber composite fabrication. Nevertheless, thermoplastic resin has a high melting temperature and low strength. In addition, bio-degradable resins (such as PLA) are eco-friendly while have low strength, stiffness as well as required high production cost due to complexities in extraction ([Senthilkumar *et al.*, 2018](#)).

There are enormous researches regarding synthetic and natural fiber composites that put us in a precarious position regarding fiber selection of the composites based on the fabrication process, mechanical properties, cost, environmental effect as well as sustainability. In this article, a review is made on the natural and synthetic fiber composite, where matrix materials are polymer particularly, thermoplastic, thermosetting and bio-degradable. A review based on the properties, performance, cost, the environmental effect has been done. Section "Comparison of Properties" describes comparison among the properties of natural as well as synthetic fiber composites, Section "Performance of Natural and Synthetic Fiber Reinforced Polymer Composites" outlines the performance of natural and synthetic composite, cost of the composite is stated in Section "Cost of Composites" and finally, the environmental effect is deliberated in Section "Environmental Effect".

Comparison of Properties

Mechanical properties of natural fibers (such as jute, coir, bamboo, banana, sisal, flax fiber) and synthetic fibers (for example, nylon, glass, kevlar and carbon) are described in the previous Section. These fiber properties are modified when they are incorporated in the matrix to obtain the desired criteria of the composite. Sometimes the related fibers are chemically treated for better performance. Thermoplastic material needs to be heated at their melting temperature whereas curing material need to add for

thermosetting matrix material. The respected data for synthetic polymer composites are collected from different sources and represented them as a range in **Table 3**. Mechanical properties particularly tensile strength, flexural strength, Young's modulus as well as flexural modulus of synthetic fiber polymer composites are listed in **Table 3**.

From **Table 3**, it is observed that tensile as well as flexural properties have ranges. This is because to obtain better performance different researcher modified the fiber through different treatments. In addition, the researchers also modified the matrix (for example, PP is modified by maleic anhydride by grafting process), fabricate the composite using modified materials and obtained the modified results. Sometimes the advanced process (such as an advanced manufacturing process, 3D printing) was used for fabrication to attain better performance (Dickson *et al.*, 2017). In this article, mechanical properties of raw and modified synthetic fiber polymer matrix composites are listed as a range. The ranges of tensile strength, flexural strength, Young's modulus and flexural modulus for synthetic fiber polymer composites are 0.7–1600 MPa, 15–850 MPa, 0.7–92 GPa, and 1–18 GPa respectively.

Mechanical properties of natural fiber polymer composites are listed in **Table 4**. Usually, mechanical properties of the composites change with the volume fraction of the fiber. However, in this article, only maximum value and the minimum value of a particular criterion have been considered ignoring the volume fraction of the fiber and represented them as a range. Moreover, different authors use different standard methods (ASTM) to measure the mechanical properties which are not highlighted in this article. Sometimes synthetic fibers are chemically modified to attain desirable properties.

From different studies, it is found that tensile strength of the composites increases when the reinforcing materials are mat, fabrics, nano form or due to new additive fabrication method. From [Table 4](#), it is observed that flexural strength and modulus of natural fiber polymer composite is higher as compared to tensile strength and Young's modulus respectively. Mechanical properties of the composites vary according to the matrix material as well as fiber reinforcing material. Natural fiber PP composite showed better tensile strength as compared to natural fiber polyester composites. In addition, natural fiber low density polyethylene composites show less mechanical properties compared to natural fiber polypropylene composites. However, natural fiber polylactic acid composites perform satisfactorily regarding mechanical properties, as shown in [Table 4](#).

According to [Tables 3](#) and [4](#), mechanical properties of synthetic and natural fiber polymer composites are different. In the case of natural fiber, diameter is different in different regions, thus the cellulose and other contents are also different. As a result, fiber properties are also varied and hence composite properties is varied. In the case of synthetic fiber, this variation is less compared to the natural fiber. Though mechanical properties of natural fiber polymer composites are lower they are partially or fully biodegradable compared to synthetic fiber polymer composites except for natural fiber biodegradable polymer composites. From [Tables 3](#) and [4](#) it is observed that, mechanical properties of synthetic fiber polymer composite are higher for a specific matrix material. For example, the range of tensile strength for synthetic fiber polypropylene composite is 20–1600 MPa, whereas that of natural fiber polypropylene composite is 3.2–277 MPa. That means synthetic fiber polymer composites have wide range of tensile strength. Similar phenomenon is also found for other properties.

Performance of Natural and Synthetic Fiber Reinforced Polymer Composites

In this Section, performance of natural as well as synthetic fiber polymer composites is highlighted. The adhesion between the interface of the fiber and matrix leads the performance of the composites. Natural fibers are cheap, eco-friendly, lightweight, as well as competitive with synthetic material regarding material properties. To increase the performance of the bio-based fiber composite the raw material such as fiber and matrix material are chemically or physically modified. The performance of the natural and synthetic fiber polymer composite is shown in [Table 5](#) at different artificial damage conditions (such as a hole, indentation, thermal aging, moisture and weathering).

From [Table 5](#), it can be stated that the performance of natural fiber composite is better as compared to synthetic fiber composites. The loss of tensile strength is less in case of natural fiber polymer composites as compared to synthetic fiber polymer composites. However, due to gamma radiation the performance of natural fiber polymer composite has enhanced. The Young's modulus of synthetic fiber polymer composite shows a higher range as compared to natural fiber polymer composites. Due to time-bound other polymer and fiber matrix performance is not collected. Usually, Due to different treatments on the fiber as well as matrix increase the interfacial adhesion. As a result, the performance of the composite is increased. High-performance fiber leads the high performance polymer composite industries. That means in the case of natural fiber the adhesion may be better compared to synthetic fiber polymer composites. Some of the polymer matrix composites perform satisfactorily in the aerospace and navy where performance of the polymer composite properties (strength, stiffness, and resistance to the hostile environment) are controlling factor. In addition, some application composite needs to sustain at high temperature where bio-based polymer composites will not perform satisfactorily. Thus, it is desirable to improve the performance of the composite regarding the reinforcing properties. To improve the performance it is needed to align the molecule of fiber along the fiber axis compared to randomly oriented fiber. A good number of scientists are involved in improving the performance of the composite by different treatments. Performance (strength and Young's modulus) of natural fiber polymer composite in an outdoor environment is influenced by different factors such as moisture, temperature, ultraviolet radiation and microorganism activities. The natural fibers have

Fig. 2 Cost of (a) natural and (b) synthetic fiber composite (30/70) in dollar (US\$).

better performance compared to synthetic fibers as well as their composites. Moreover, natural fibers emit oxygen and absorb CO₂ in the air while synthetic fibers emit CO₂ only. Synthetic fibers have a severe environmental impact as they need fossil fuels for primary production whereas natural fibers have better environmental performance because they consume solar energy and few fossils. Last but not least, high performance synthetic fiber composites are used in high speed and precision machinery, robotics and structural material.

Cost of Composites

One of the important reasons for increased use of natural fiber is its cheap price as compared to synthetic fiber. The price list of the bio-based fiber as well as the synthetic fiber is given in Table 6. From Table 6, it is clear that the synthetic fibers are 4–3000 times more expensive than the natural fiber. The elongation properties of polyester and epoxy gradually increased and due to this incremental property, their price is also gradually increased as shown in Table 6.

As natural fibers are of low density, the transportation cost of the natural fiber is less as compared to synthetic fiber. In addition, due to the cheap price of the natural fiber when they are incorporated in the matrix, the price of the composite will be cheaper compared to synthetic fiber polymer composites. A comparison between the fabrication cost of natural fiber (jute, coir, bamboo and banana) polypropylene composites as well as synthetic fiber (glass, kevlar, nylon, and carbon) polypropylene composite sis shown in Fig. 2. For cost estimation, the prices of PP, natural fibers as well as synthetic fibers are considered according to Table 6.

From Fig. 2, it is clear that the raw material price to fabricate a 30/70 natural fiber polymer composite is lower as compared to synthetic fiber polymer composite. For natural fiber, the price lies between \$1.5 and \$7.8, whereas it lies between \$1.5 and \$906 for synthetic fiber polymer composite. In this article, five types of natural fiber, synthetic fiber as well as polymer matrix are considered for cost estimation. The cost of the bio-fiber polymer composite is reduced compared to synthetic fiber composite by a certain percentage which cannot be ignored as shown below.

Case I: Cost analysis for 1:3 fiber ratio of Glass PP composite in the contest of Bangladesh

Cost of glass fiber = \$1.3

Cost of PP = \$0.42

When 30% glass incorporated in the PP the cost of raw material is = \$1.799.

Case II: Cost analysis for 1:3 fiber ratio of Jute PP composite in the contest of Bangladesh

Cost of Jute fiber = \$0.21

Cost of PP = \$0.42

When 30% jute fiber is incorporated in the PP, the total cost of raw materials is = \$0.63

Thus, the reduction of cost (\$) due to bio-fiber incorporation in the composite is = 64.98%.

Based on the above contemplation it can be concluded that 30% incorporation of natural fiber, jute fiber, in the PP matrix, total 64.98% cost will be reduced. In addition, the total price of the composite will be reduced depending on the percentage of bio fiber loading. Similarly, the price will be reduced when any bio-based fiber incorporates in any other natural or manmade polymer matrix. No other cost rather than the cost of raw materials is considered during composite cost estimation.

Environmental Effect

Natural fiber has a great impact on the environment. Natural bio-based fibers emit oxygen and absorb CO₂ during the primary fiber production. Thus, CO₂ foot print of the natural fiber is lower and they have a good impact on the composite life cycle as shown in Fig. 3. The primary material namely, fiber, is used in the composite that will be further used in the manufacturing of products. After the consumption of that product, they are recycled. When no longer recyclable it will be used as a land filled for disposal. This disposed material will be consumed by the green plant to maintain the eco-system. If there is only synthetic fiber in the composite material this life cycle will be hampered.

On the contrary, synthetic fibers emit huge CO₂ during primary material production as well as product manufacturing, which have bad impact on the green globalization. CO₂ foot prints of natural as well as synthetic material are listed in Table 7. From Table 7, it is detected that CO₂ foot print of natural fiber is lower as compared to the synthetic fiber. Though natural fibers have

Fig. 3 Natural fiber composite life cycle.

The International Journal of Life Cycle Assessment 7 (5), 277–282.

CO₂ foot print, they absorb CO₂ as well as emit oxygen that has a good impact on the green globalization. Furthermore, bio-based materials are naturally bio-degradable while synthetic materials are not bio-degradable except bio-degradable man-made fiber and matrix material. In addition, health hazard condition occurs during the production of the synthetic composite. However, natural fibers have OH group which leads them to biodegrade and due to this property, they show dimensional instability, anisotropic behavior as well as low thermal behavior (Célino *et al.*, 2014).

Furthermore, when the reinforcing materials are incorporated in the matrix, in case of natural fiber OH group reacts with the matrix material and the related compound is formed. Due to this OH group, the bio-based composites are hydrophobic and they absorb moisture from the air and the interfacial bond between the fiber and matrix degrade after a certain time. Moreover, as synthetic fibers require fossil, their cost is higher compared to natural fiber. Last but not least; natural fibers will increase manpower in the developing country as well as the climate without hampering the green globalization.

Conclusion

A review of properties, performance, cost and environmental benefits for natural and synthetic fiber reinforced composites is conducted in present article. Both natural and synthetic fiber composites have a wide range of mechanical, thermal and other properties. In comparison, synthetic fiber composites generally have better properties. However, natural fiber reinforced composites showed better performance and the cost of producing natural fiber composites is much lower as compared to that of synthetic fiber reinforced composites. Natural fiber reinforced composites also have better impact on environment as compared to the synthetic fiber reinforced composites.

Natural Indigo for Textiles: Past, Present, and Future

Introduction

Colorants including both dyes (which are water-soluble) and pigments (which are water-insoluble) from natural sources, particularly from the plants, have a long tradition throughout world history until the invention of synthetic dyes in 1856 in England. They can be extracted from the whole plant (e.g., weld), the leaves (e.g., woad, indigo species), the roots (e.g., madder), the flowers (e.g., saffron), the fruits (e.g., common buckthorn), the shell (e.g., Persian nut), the bark (e.g., oaks), or the skin (e.g., onions) (Cardon and du Chatenet, 1990). Tyrian purple, one of the most exquisite shades of purple, which had dominated the luxurious works of artists and served as a status symbol for the Royals throughout the history, used to come from the Phoenician city of Tyre (presently a part of Lebanon) and was obtained from sea snails of the Murex family. Chemically it was a complex mixture of indigoid colorants and was rare and exclusive, therefore, it was used to imitate the Tyrian purple to achieve similar shades using other colorants (Cardon, 2009). Examples of these imitations were described in the Babylonian and Egyptian texts, such as the dyeing of wool in two steps, first with woad or indigo, then with madder and extracts of certain insects (Cardon, 2007). Interestingly, Tyrian purple and indigo have very similar chemical and physical properties and both of them belong to the same class of colorants known as vat dye (Clark *et al.*, 1993).

Indigo is a fascinating blue colorant that has always been adored throughout the whole world due to its brilliance and stability of the hue it produces when applied on textiles. The best source of color-fast blue dyes is indigo plants (see Fig. 1), scattered in many different botanical families found in many diverse natural environments (Balfour-Paul, 1998). It is obtained as an insoluble pigment from the leaves of indigo plant and has to be chemically converted into water-soluble dye for use in textile coloration (John *et al.*, 2019). The predominant sources of natural blue dyes are included in Table 1. Indigo (*Indigofera tinctoria*) is a plant of tropical climate. However, in Europe blue colorant was obtained from another plant of a related family, locally available woad (*Isatis tinctoria*), to imitate the most prestigious antique color of purple (Cardon, 2009). The variety of indigo plants provides different shades of blue due to the presence of different side components in its chemical structures; therefore, a distinction between different sources is easily possible. Today the synthetic indigo is the most predominant dyestuff in use with approximately thousands of tons produced annually due to the popularity of denim industry (Roessler *et al.*, 2002; Głowacki *et al.*, 2012; Buscio *et al.*, 2014; Chavan, 2015). However, this article will focus on natural indigo only.

Historical Background

Archeological evidence shows that indigo had been used for more than 4000 years in India, Egypt, and China. Wherever the indigo bearing plants were available, the ancient inhabitants found a way to extract colorant from the plants for use in coloration of

Fig. 1 Indigo plant for natural colorant extraction. Pictures taken from a ruined Indigo factory (inset) in Bhatpara, Gangni, and Meherpur, Bangladesh; built in 1778 during British rule of India.

Table 1 Sources of major natural blue colorants from plant species

Plant species: Botanical name	Plant species: Common name	Origin	Reference
<i>Isatis tinctoria</i> L.	Woad	Europe	(Biertmpfel and Wurl, 2009)
<i>Periscaria tinctoria</i> (old name <i>Polygonum tinctorium</i>)	Polygonum or Japanese indigo	Northern/Central Italy, Germany, Japan, China, Korea	(Biertmpfel and Wurl, 2009; John and Angelini, 2009; Maier <i>et al.</i> , 1990)
<i>Indigofera tinctoria</i>	Indigo, <i>Nila</i>	Tropical countries in Asia such as Indian subcontinent, China, Thailand, Malaysia, Cambodia, Laos, Philippines, Myanmar, Indonesia, India, Pakistan, Sri Lanka, America, and Africa	(Linh, 2009)
<i>Indigofera argentea</i>	–	Egypt (e.g., Nubia, Kordofan, Sennar), Abyssinia	(Melo, 2009)

different objects including textiles. Although there are different plants other than indigo that provide blue colorant, it is interesting that indigo gained the most popularity, even in ancient times, despite the complex way of extracting and developing this color on textiles that needed to be followed (Clark *et al.*, 1993).

Indigo has been used for various purposes other than textile dyeing, for example, as a medicinal substance in the Middle East, as ingredients of cosmetics including hair dye and skin ointment, and as religious symbolism in Judaism (Scholem and Margulies, 1980). It was used in India in the protohistoric city of Mohenjodaro in the Middle to Bronze Ages of the second millennium BCE. In fact, the word *indigo* derived from the Greek word *indikou* or Latinized *indicum*, which refers to a substance from India. The cultivation of blue dye bearing plants from local sources had been established in various parts of the world, and a network of trade had been established to import of those blue dyes in the West to meet the growing demand in terms of both quantity and quality. Natural indigo pigment was a very rare commodity in Europe until 14th century in oppose to the available blue color from indigenous woad, which was inferior in quality compared with that of Indian indigo. Anti-indigo sentiment was very powerful among the woad growers in Europe, which led to describe it as “devil’s food or devil’s dye” with restriction of use in several European countries (Clark *et al.*, 1993).

The history of indigo has direct relation with the colonization by the European settlers throughout Asia and Africa, and in particular with the emergence of commercial plantation in the colonies from the 17th century. Large-scale cultivation started in the Caribbean and Central and South America under direct supervision of the European planters with the use of cheap labor in the form of slavery (Kumar, 2012). Although India was famous for tropical indigo plants (Gittinger, 1982) and central to the early history of indigo (Balfour-Paul, 1998), it was nowhere in the international map until the British imperial rule resurrected the plantation due to the shortage of indigo supply sourced from other parts of the world. The plantation in Bengal (presently divided into Bangladesh and West Bengal of India) was a no-brainer due to the then British rule and rich climate suitable for indigo plant; however, it took a relatively long time to start due to priority trials in various parts of India, such as Madras and Bombay, where it was not successful. In fact, from the beginning of the 19th century Bengal emerged as the leading supplier of indigo to the world (Kumar, 2012) and remained as the last frontier of natural indigo cultivation before the advent of synthetic dyes. Over time indigo manufacturing geographically pivoted into lower Bengal in the subcontinent (see Fig. 2), and attracted 20.26 million rupees of capital with a direct and indirect employment of 1.36 million in the 19th century (Ray, 2004). The fate of natural indigo is directly linked with the fate of Bengal peasants, who were forced to plant indigo. Although indigo cultivation was native to the Bengal, the commercial scale plantation was more of a colonial enterprise to meet the extensive demand in Europe. As a result, a movement by the peasants against the planters took place between 1859 and 1862, which is known as the “indigo rebellion” or “blue mutiny” and wiped out the entire indigo industry from lower Bengal to North Bihar (Kumar, 2012).

Indigo Production

Blue colorants come from different indigenous varieties of plants. In India, this comes from the *indigofera tinctoria*, while in Europe it comes from *Isatis tinctoria* (see in Fig. 3). There are about 250–300 species of *Indigofera* across the world but not all species yield dye. *Indigofera tinctoria* produces superior quality dye to any other species (Clarke, 2004) and it is, therefore, also referred to as “true indigo” (Teanglum *et al.*, 2012). Good quality indigo colorant from the Bengal contains as high as 60% indigo pigment (Clark *et al.*, 1993).

Indigofera tinctoria L. species have straight branches approximately 1 m in height and grow in a bush. The leaves are long, egg-shaped, and arranged in double alternate within the branch. The branches are 1.5 to 2.5 cm long, thin, and narrow at the stem. The flowers grow in cluster and are white and purple in color. The *indigofera* seeds are planted from February to May and harvested from August to October (Reid, 1887). After harvesting, if the roots are left, new plant will continue to grow. *Indigofera* sp. is a leguminous plant, whose roots are rich in nitrogen. Thus it can be used as a rotational crop that enriches the soil for paddy production (Balaram, 2011). Extraction of indigo involves dipping the leaves at the right temperature with fermentation and reduction process to allow the indigo precursors to leach out of the leaves. To give an estimation, from 100 kg of plant leaves, 3 kg of indigo powder can be produced, which contains 300–400 g of indigo pigment (Linh, 2009). The amount of dye that can be obtained from woad is much less than that from *Indigofera* species (Clark *et al.*, 1993). According to Perkin (1900), a good sample of indigo contains 61.4% indigo blue, 7.2% indigo red, 4.6% indigo brown, 1.5% indigo gluten, 19.6% mineral, and 5.7% water.

Indigo Chemistry and Traditional Coloration Process

Indigo, like any other natural dyes, does not come in a ready to use state from the plant. It belongs to a class of vat dyes, which are insoluble in their natural state. It is one of the most light-stable organic dyes, which explains its wide use throughout the history (Sousa *et al.*, 2008; Melo, 2009). The structure of indigo can be reduced to form leuco-indigo, which is almost colorless (see Fig. 4; Cardon and du Chatenet, 1990; Clark *et al.*, 1993). Indigo is also known as indigo blue and indigotin (C.I. Vat Blue 1, C I 7300,

Indigo and tyrian purple – From ancient natural dyes to modern organic semiconductors, Israel Journal of Chemistry 52 (6), 540–551. doi:10.1002/ijch.201100130.

CAS number: 482/582-89-3, IUPAC name 3H-indol-3-yl, 2-(1,3-dihydro-3-oxo-2H-indol-2-ylidene)-1,2-dihydro-, chemical formula $C_{16}H_{10}N_2O_2$) (Chavan, 2015).

Indigotin is a precursor of indigo and can be extracted from the plants, as a solution of indican, a water soluble indoxyl glucoside, which is fermented by an enzyme called glucosidase to produce indoxyl via hydrolysis. Indoxyl reacts further with another indoxyl molecule to produce indigo or reacts with isatin to produce indirubin, known as a red shade of indigo Balfour-Paul (2006), often found in different ratio in indigo leaves. Fig. 5 shows transformation of indoxyl in two different shades (Cardon, 2007). Traditionally many substances were introduced in a dye-bath to create and accelerate the fermentation process, such as madder roots, wheat bran, honey, dates, raisins, plant seeds, and glucose (Meksi and Mhenni, 2015). Today, other than natural fermentation, there are other procedures to reduce indigo such as chemical reduction, electrochemical reduction, catalytic hydrogenation, and electrocatalytic hydrogenation (Chavan, 2015).

Since indigo dye extraction was not a straightforward process, the British planters in Bengal developed an expansive manufacturing process, which involved systematic processing of leaves in large “factories” to turn indigo into a dye, with mechanization, steam power, and use of chemical substances (Kumar, 2012).

The traditional recipe of dyeing fabrics with indigo involves the following ingredients and process (Chavan, 2015).

- 250 g of locally available lime in lump form, mixed with 2 l water to make a smooth slurry
- 500 g wood ash mixed with 2 l water
- 500 g of casetora seeds (methi), boil with 2 l water for 1 h
- 500 g of indigo paste

The indigo paste is thoroughly mixed with 15 l of water and the other ingredients mentioned above in a vat, a mud pot. The vat is closed with a lid or piece of fabric and allowed to ferment for 7 to 10 days, until the appearance of a yellowish green color is seen, which indicates a complete reduction of indigo. The fabric to be dyed is then wetted and dipped into the solution, squeezed thoroughly and exposed to air for the formation of indigo color through oxidation. Depending on the depth of the blue shade required, the process of dipping and exposure to air continues for 6 to 10 times. The same vat is used continuously for several months with the fresh addition of indigo and other ingredients. The indigenous knowledge of indigo dyeing is still practiced in Bangladesh, India, Japan, and some parts of Africa and America, however, is rapidly disappearing due to the competition with synthetic dyes in the global market.

Natural Versus Synthetic Indigo

The history and subsequent demise of natural indigo are linked to the birth of chemical industry also. A significant milestone for the chemical industry was achieved when William Henry Perkin, an 18-year-old chemist from England, developed the first synthetic dye “Mauvine” in 1856 (OpenLearn, 2007). Since then a relentless competition had developed between the British and the German scientists to imitate the naturally available dyes such as alizarine, indigo, etc. Perhaps this could be considered as the beginning of the end of natural indigo production, including Bengal (Balfour-Paul, 1998; Cardon, 2009). At that time the big synthetic dye manufacturers were also suppliers (Geigy) or merchant (Hoechst, Baeyer, or Badische Anilin- und Soda-Fabrik (BASF)) of natural dyes, with production and distribution of natural extracts, preparations, and synthetic dyes (coal tar dyes) were often all carried out as a single business entity (Engel, 2007).

German chemist Adolf von Baeyers (Nobel Laureate of 1905) first discovered the chemical structure of indigo in 1883 (Głowacki *et al.*, 2012). For the first time in 1897, German synthetic dye company BASF launched its version of synthetic indigo, “pure indigo from BASF,” in the market, with a commercially successful route (Clark *et al.*, 1993). The use of the relatively cheap aniline as the raw material, and subsequent discovery of sodamide as the condensation agent, which lowered the overall reaction temperature from 300°C to 200°C, were the two key factors in the economic success of the BASF–Hoechst indigo synthesis (Chavan, 2015). This development of synthetic indigo cost BASF 900,000 euro, 30 years of research, and 152 German patents by 1900 (Brunck, 1901; Głowacki *et al.*, 2012), however in 1899, indigo sales earned enough to pay for the amortization and dividends on the capital for BASF (Abelshauser *et al.*, 2004). Soon other German companies followed and started to manufacture synthetic indigo (Kumar, 2012). Synthetic indigo become the symbol of dominance of the German chemical industry over its British rivals.

The arrival of synthetic indigo further provoked the adversaries between imperial and colonial or between colonial and native interests, and interrupted the social hegemony of the world (Kumar, 2012). The marketing of synthetic indigo created tension within imperial Britain with colonial interest, and threatened the investments of British expatriate planters in India. In fact, by 1900, the production of synthetic indigo reached to a point that was equivalent to a quarter million acres in India. In 1914, the export of natural indigo from the undivided India including Bengal fell to 1000 t, which was 19,000 t and 8000 t in 1897 and 1901 respectively (Clark *et al.*, 1993). By 1914, BASF was producing 80% of the world’s synthetic indigo (Freeman, 1997). Since Germans were outside the control of imperial Britain, it could do little to stop the tide of this global trend. As a result the demise of natural indigo of Bengal was not only linked to the protest by the native Bengal peasants but also the coincidental development of the synthetic chemical industry (Travis, 1993; Kumar, 2012).

Future Trends

With the increasing concerns on health and environment and the effect of global climate change, consistent efforts have been taken to reduce the adverse impact of the production process of synthetic indigo. As a result, the focus turned to natural dyes as they are from renewable sources and involve little chemical reaction and sometimes have a curative effect on health (Patel, 2011). During the end of the 19th century, the successful replacement of natural indigo was possible because synthetic was cheap and consistently pure, greater than 90%, with no presence of indigo red, indigo brown, or indigo gluten, which imparts certain shades on indigo blue (Perkin, 1900). Whereas the purity of extracted indigo from tropical *Indigofera tinctoria* varies from 20% to 90% (Perkin, 1900) while purity of indigo extracted from *P. tinctorium* ranges from 2% to 12.3% (John *et al.*, 2019). In addition, extraction of natural indigo is also inefficient as at least 40% indoxyl is lost during transformation to indigo (Garcia-Macias and John, 2004). Therefore, to become an alternative to synthetic indigo, the purity of the natural indigo remained an important consideration. A European Commission-funded project Sustainable Production of Plant-derived Indigo (see “Relevant Website section”) was launched in 2000 with an aim to reintroduce indigo-yielding crops to European agriculture and to provide a means for European farmers to produce natural indigo with high purity. The project worked with nine partners in Spain, Finland, Germany, Italy, and the UK and examined woad (*Isatis tinctoria*) and *Polygonum tinctorium*, resulting in purity up to 60% (John *et al.*, 2019).

Although it seems the battle for dominance of natural indigo versus synthetic indigo will continue, both will keep their respective places. The growing interest of natural indigo may also continue to rise, but given the market size and requirements, it will always be a niche market among the enthusiasts. The companies which are active on the market in selling natural dyes in ready powder form include De la Robbia of Milan, Allegro Natural Dyes from USA, Livos Pflanzenchemie Forschungs und Entwicklungs

Fig. 6 Indigo dyed saree made by Aranya crafts in Dhaka, Bangladesh.

GmbH from Germany, Bleu de Pastel from France, or Fibrecraft from UK (Hill, 1997) and Aranya crafts from Bangladesh. Fig. 6 shows a Saree dyed from natural indigo made by the Aranya crafts, Bangladesh.

Similarly synthetic indigo, with market monopoly, is also trying to reduce its environmental footprint through green chemistry such as replacing reducing agent sodium dithionite with reducing sugar (Saikhao *et al.*, 2018), microbial production/synthesis of indigo (Ma *et al.*, 2012; Chavan, 2015), and alternate environment friendly technology of indigo dyeing. In addition, an entirely new concept of blue denim production has emerged without indigo, which may drastically change the landscape (Chavan, 2015). However, the indigo colorant with all possibilities of sources, such as natural, synthetic (including recycled), and microbial will be in the market side by side, with different volumes over time (Hill, 1997; Cardon, 2009).

Conclusion

After thousands of years, natural indigo still continues to be cultivated, produced, and used throughout the world, but in a remarkably low quantity in comparison to its historical use before the advent of synthetic dyes. Provided the big volume of synthetic dyes being industrially produced and used at present, it is very unlikely that the natural indigo will be able to regain its fame and dominance anywhere in the near future. However, it will certainly continue to be adored by nature-loving consumers and enthusiasts. Certainly more investment and effort in research to enhance the productivity, purity, and processing of natural indigo will strengthen its chance of healthy coexistence with synthetic indigo.

Introduction

Fiber reinforced polymer composite (FRPC) materials consist of polymer matrices imbedded with textile fibers as fillers (Groover, 2004). The common thermoplastic polymers that are used as matrices are polypropylene (PP), polyethylene (PE), and polyvinyl chloride (PVC). On the other hand, phenolic, epoxy, and polyester resins are the most common thermosetting matrices used in composite fabrication (Malkapuram *et al.*, 2008). The use of FRPCs is increasing significantly due to their low weight, high specific modulus, low cost, appropriate strength, biodegradability, and eco-friendliness. As reinforcements, the synthetic fibers, such as glass and carbon, traditionally dominate in composite manufacturing. However, the natural fibers have emerged as attractive alternatives for use as fillers and reinforcements in polymer composites that do not require very high mechanical performance (Nabisaheb and Jog, 1999). The natural fibers are biodegradable, renewable, cost-effective, and eco-friendly materials and they can solve the disposal problems associated to polymeric composites.

Natural fibers can come from both plant and animal origins. Fibers that come from plants can be classified into three categories: (1) Bast fibers (produced in plant stems, such as jute, kenaf, flax, hemp, ramie, *etc.*), (2) leaf fibers (produced in the leaves of the plants, such as pineapple, sisal, abaca, banana *etc.*), and (3) seed-hair fibers (grown around the seeds, or fruits of the plants such as cotton, coir, kapok *etc.*). Table 1 presents a list of common natural fibers and their producing countries.

Bast fibers exhibit good mechanical properties and therefore, they are preferred for structural application in composites (Gay *et al.*, 2003). The common properties that are considered for the selection of reinforcements in composite fabrication are tensile strength, elastic modulus, specific elastic modulus, density, compatibility with matrix material and moisture regain. The mechanical properties of key natural fibers, in comparison to glass fiber are presented in the Table 2 and the chemical composition of some selected natural fibers are shown in Table 3. This article introduces green composites and gives an overview of partly biodegradable jute-FRPCs that can reduce the environmental impact of nonrenewable polymers.

Green Composites

Green composites include at least one biodegradable component, either matrices or fillers, or both (La Mantia, and Morreale, 2011). They can be divided into two groups, namely, (1) partially biodegradable or partially green, and (2) fully biodegradable or fully green composites. In partially green composites, either matrix material or reinforcement is derived from the natural resources. The combination may include natural fibers such as jute, flax, *etc.* As for example reinforcements or fillers, and synthetic polymers such as PP, or PE as the matrix material; or synthetic fibers such as glass, or carbon fibers as reinforcement and polylactic acid (PLA) as the matrix. On the other hand, fully green and biodegradable composites are those that include both filler and matrix materials derived from natural resources. For example, a green composite would include a natural fiber is used as a filler and a natural polymer such as PLA and polyvinyl alcohol *etc.* as a matrix. If a composite material is completely biodegradable, that is, both filler and matrix are from natural origin, it is also identified as a biocomposite (Cheung *et al.*, 2009).

Table 1 Common natural fibers and their producers

Fibers	Plant origin	Major producers
Cotton	<i>Gossypium sp.</i>	China, India, USA
Jute	<i>Corchorus sp.</i>	Bangladesh, India, China
Flax	<i>Linum usitatissimum</i>	Canada, France, Belgium
Hemp	<i>Cannabis sativa</i>	China, France, Philippines
Kenaf	<i>Hibiscus cannabinus</i>	Bangladesh, India, USA
Ramie	<i>Boehmeria nivea</i>	China, Brazil, Philippines, India
Sisal	<i>Agave sisilana</i>	Tanzania, Brazil
Coir	<i>Cocos nucifera</i>	Bangladesh, India, Sri Lanka

Green composites are finding notable applications in the areas like food packaging, agriculture, composting bags, furniture, etc. **Fig. 1** presents the EU market shares of different FRPCs in the year 2010.

Choices of Matrix for Green Composites

PP, PE, epoxies, and biopolymers such as PLA, polyhydroxybutyrate (PHB) are the most commonly used polymer matrices for fabrication of FRPCs. The common biopolymers used as matrices are PLA, PHB, soy-based plastics, cellulose polyesters, starch-based bioplastics, vegetable-oil derived bioplastics, poly (trimethylene terephthalate), biopolyethylene etc. The global consumption of bioplastics increased significantly from 15,000 tons in 1996 to 225,000 tons in 2008 (Pilla, 2009). Mechanical properties and prices of few biopolymers with reference to PP are listed in the **Table 4**.

Different surface treatments of natural fibers, namely silane, acetone and alkali treatment, etc. and coupling agents (maleic anhydride, potassium permanganate, etc.) are normally used to enhance the interfacial adhesion between fiber and matrix. The

Table 4 Properties of natural polymers in relation with polypropylene

Polymer	Density (g/cm ³)	Melting point (°C)	Tensile strength (MPa)	Young modulus (GPa)	Elongation at break (%)	Price (US\$/kg)
Thermoplastic starch	1–1.39	110–115	5–6	0.125–0.85	31–44	5.5
PLA	1.21–1.25	150–162	21–60	0.35–3.5	2.5–6	2.42

**Fig. 2** Comparison of different composite forming techniques in terms of cost and batch size. Graph drawn by CES EduPack software.

desirable mechanical properties of a composite are obtained when the applied load is effectively transferred from the matrix to the reinforcing fibers through the interface.

Manufacturing Techniques of Biocomposites

The existing manufacturing techniques for biocomposites are hand lay-up, filament winding, pultrusion, extrusion, injection molding, compression molding, resin transfer molding (RTM), and sheet molding compounding (SMC). A comparison of different techniques is presented in Fig. 2. Compression molding (including hot and cold pressing) is a popular method for fabricating FRPCs because of its simplicity (Shah, 2013). However, this is a slow process and not appropriate for mass production. Again hand lay-up and filament winding are also low volume processes with higher relative cost index per unit. The ideal manufacturing technique for mass production is injection molding due to its high processability; although the degradation of reinforcing fiber may happen during processing (Arao et al., 2015). SMC and extrusion molding are also suitable for mass manufacturing and this can bring down the relative cost index per unit. In terms of both manufacturing tolerance and labor intensity, extrusion and injection molding are best as shown in Fig. 3. SMC and RTM require medium to high labor intensity but hand lay-up and filament winding show the weakness of producing products with higher manufacturing tolerance. The key manufacturing techniques used for plant fiber reinforced composites with corresponding percentages used are shown in Table 5.

Fig. 3 Comparison of different composite forming techniques in terms of manufacturing tolerance and labor intensity. Graph drawn by CES EduPack software.

Table 5 Manufacturing techniques used for plant fiber based composites

Composite type/matrix type	Manufacturing technique	Percentage used (%)
Plant fiber reinforced composite/thermoset	Compression molding	30
Plant fiber reinforced composite/thermoplastic	Compression molding	60
Plant fiber reinforced composite/thermoplastic	Injection/extrusion molding	10

Note: Shah, D.U., 2013. Developing plant fibre composites for structural applications by optimising composite parameters: A critical review. *Journal of Materials Science* 48 (18), 6083–6107.

Challenges for Natural Fiber Reinforced Polymer Composites

The main limitations identified in the natural FRPCs are moisture absorption, decreased durability, weak interfacial adhesion between the fiber and matrix, and relatively poor mechanical properties (Gassan and Gutowski, 2000; Haq *et al.*, 2018). Degradation causing exposure to outdoor environment is another vital issue of natural FRPCs. The moisture absorption properties of plant based natural fibers confines the outdoor applications of natural FRPCs. Several methods, namely surface treatment and addition of coupling agents, are employed with the purpose of decreasing moisture absorption and enhancing interfacial bonding and mechanical properties of the FRPCs (Ahmad *et al.*, 2006; NabiSaheb and Jog, 1999). Percentages of moisture absorption by some selected natural fibers are given in Table 2. It is revealed that the lower the moisture content in fiber, the higher the mechanical properties of the fiber as well as FRPCs. Moreover, lack of innovation in appropriate commercial manufacturing techniques and composites having higher mechanical properties with natural fibers as reinforcement are also limitations in the field of natural fiber based polymer composites. Another disadvantage of using natural fibers as reinforcements is the low processing temperature required for the fabrication of composites. The maximum acceptable processing temperature is 200°C, beyond this limit, plant based natural fibers were found to degrade and shrink that consequently cause lower mechanical performance of the green composites.

Composite Architecture and Fiber Parameters

Factors like fiber geometry and orientation, packing arrangement, and volume fraction generally govern the mechanical performance of FRPCs. Among them, fiber volume fraction (V_f) is the most important factor that influences the properties of FRPC directly. It is found that the mechanical performance of FRPCs increases with an increase in V_f up to a certain limit.

Fig. 4 A comparison of specific strength vs. specific stiffness between natural and some selected man-made fibers. Graph drawn by CES EduPack software.

High fiber volume fraction is necessary for better composite performance. However, for better mechanical performance, distribution of both fiber and matrix should be uniform along with the component. The longitudinal modulus of FRPC is determined by the simple rule of mixtures approach, which is represented by Eq. (1);

$$E_L = E_f V_f + E_m (1 - V_f) \quad (1)$$

where E_L is the longitudinal modulus of elasticity, (i.e., the direction of parallel fibers oriented in the longitudinal direction), V_f is the fiber volume fraction of the composite, E_f is the modulus of the fiber, and E_m is the modulus of the matrix.

The Fiber–Matrix Interface

The interfacial behavior and adhesion between fiber and matrix is a very important factor that determines the performance of FRPCs. The interface acts as a medium for transferring any externally applied tensile force to the reinforcing fibers through shear stresses over itself. The interaction between fiber and matrix in a FRPC can be enhanced through surface modification (chemically or physically) of natural fibers and textile substrates made of natural fibers. The plant based natural fibers are strongly hydrophilic in nature as they contain many hydroxyl (–OH) groups in their cellulosic polymer chains. This hydrophilicity of natural fibers is a possible reason for incompatibility, poor interfacial adhesion, and dispersion problems with hydrophobic polymer matrices. Different experimental works show that the surface modification of plant based natural fibers such as acetylation, silylation, and other chemical treatments decrease their hydrophilicity and moisture absorption capacity (Fowler *et al.*, 2006).

Jute Fiber

Jute is one of the plant fibers found abundantly in nature and can be easily used as a reinforcing fillers for the fabrication of FRPCs. Cellulose is the major chemical composition for all the plant based natural fibers, even though the amount of different chemical composition (such as cellulose, hemicellulose, lignin, and other extracts) varies from fiber to fiber (Table 3). Among the natural fibers, jute, flax, and hemp are suitable for fabrication of structural, automotive composites and many other value-added applications mainly because of their tensile properties. The different mechanical properties of the major natural and manmade fibers are shown in Fig. 4. Comparing the specific strength (tensile strength/density) and specific modulus (elastic modulus/density) of natural fibers and manmade fibers, it is evident that specific strengths of carbon and E-glass fiber are higher than that of all natural fibers. However, the specific modulus of E-glass fiber is comparable to the specific moduli of jute, hemp, flax and kenaf fibers. This data proves that the properties of the lignocellulosic bast fibers such as jute, kenaf, and flax fibers are comparable to that of glass fibers.

Fig. 5 A comparison of price and specific strength of fibers used in composite manufacturing. Graph drawn by CES EduPack software.

Like other plants of natural fibers, jute plants have a capacity for absorbing a large amount of carbon dioxide (CO_2) from environment and consequently clean the air by reducing the carbon content in air (Holbery and Houston, 2006). Jute fiber is called as bast fibers since it is produced from the plant stem. The most commonly cultivated varieties of jute in Bangladesh and India are *Corchorus capsularis* (also known as white jute) and *Corchorus olitorius* (known as Tossa jute) (see Table 1). The moisture regain (%) and tensile modulus of jute fiber is very high, nevertheless the breaking elongation is very low. However, considering the low density of jute fiber, the specific modulus and strength of jute fiber are comparable to those of glass fiber (see Table 2). Besides, jute possesses very good technical properties, for a specific strength it is also one of the cheapest fibers compared with the other natural and manmade fibers as shown in Fig. 5.

The outer stems of jute plants are used to make the fiber but other parts of the plant are equally useful such as green leaves are used as vegetable, dry leaves are used as a drink, and jute stick is used as firewood, charcoal, light construction material, etc.

Jute Fiber Reinforced Composites

Several natural fibers such as jute, flax, hemp, sisal, coir, etc. have already been applied as fillers in FRPCs, however jute fiber based FRPCs have been found with moderate tensile and flexural properties (Khan et al., 2013; Mohanty et al., 2000). Jute fibers can be used as fillers for FRPCs in various forms such as chopped fibers, yarns, and fabrics (woven, knitted or nonwoven) (Sayeed et al., 2014). Fig. 6 presents a schematic diagram of different types of fiber/fabric orientations in jute FRPCs.

Based on the types of reinforcements used for the fabrication of composites, FRPCs are divided as (1) unidirectional, (2) bidirectional continuous fiber composites, or (3) discontinuous reinforcement composites (aligned or randomly oriented in the form of particulates, short fibers, and whiskers). A large number of research works have been conducted on fully biodegradable and partially biodegradable jute-FRPCs. Table 6 reviews some of the reported works on the mechanical properties of jute-reinforced composites. Here, fiber weight fraction, fabrication technique, matrices used, tensile strength, and tensile modulus are reported to compare the mechanical properties of jute fiber reinforced composites with that of glass fiber reinforced composites.

Chemical Modification of Jute Fiber

As mentioned already the natural hydrophilic fibers can be chemically treated for the enhancement of interfacial adhesion with the hydrophobic matrices. In case of jute, the interfacial adhesion can be improved by alkali treatment (Li et al., 2007), acetylation (Hill et al., 1998) and silanization (John et al., 2008) methods. Alkali treatment is the most commonly used chemical process applied for the surface modification of jute fibers and jute-based textile substrates used in FRPC fabrication. Valadez-Gonzalez et al. (1999) demonstrated that alkali treatment of fiber increases surface roughness leading to better mechanical bonding and

Abbreviations: BAK 1095: Biodegradable polyester amide; CM: Compression molding; HDPE: High-density polyethylene; IM: Injection molding; L: Longitudinal; PP: Polypropylene; PHBV: Poly(3-hydroxybutyrate-co-3-hydroxyvalerate); PLA: Polylactic acid; T: Transverse; UD: Unidirectional.

simultaneously, it also increased the exposure of cellulose polymer on the fiber surface, which enhances the number of possible reaction sites. It is reported that alkali treatment can eliminate the hydroxyl ($-OH$) groups from jute polymer system and can improve the compatibility with hydrophobic thermoplastic matrix by decreasing the hydrophilic nature of the jute (Liu and Dai, 2007). The typical reaction that takes place when alkali ($NaOH$) is applied on jute surface is presented below.

Sodium hydroxide treatment removes lignin and hemicellulose and makes the interfibrillar regions in jute polymers less dense and less rigid (Bledzki and Gassan, 1999). As a result, these fibrils can perform better in tensile load sharing through rearranging themselves easily when any tensile load is applied.

Different Forms of Jute Substrates as Composite Reinforcement

Experimental trials with all different structural forms of jute based textile substrates, such as fiber (Bisaria *et al.*, 2015; Gopinath *et al.*, 2014), sliver (Das and Bhowmick, 2015), yarn (Memon and Nakaib, 2013; Pujari *et al.*, 2015), woven (Sudha and Thilagavathi, 2015; Sayem *et al.*, 2018; Arju *et al.*, 2015), knitted fabrics (Arju *et al.*, 2015), and nonwoven sheets (Karaduman *et al.*, 2014; Sayeed *et al.*, 2014) have already done in fabrication of FRPCs using both thermoplastic (Sayeed *et al.*, 2014) and thermoset polymeric matrices (Bisaria *et al.*, 2015; Das and Bhowmick, 2015; Pujari *et al.*, 2015) individually.

Haydaruzzaman *et al.* (2010a) treated bleached fabric of tossa jute with a solution of 50%–90% oligomer urethane acrylate, 2% photoinitiator in methanol, and irradiated under UV light for 24 h before heat pressing five layers of treated fabrics to form composite laminate. They identified the best mechanical properties from the composite that was made from jute fabrics treated with 70% of oligomer, 28% methanol and 2% photoinitiator followed by UV radiation. Kafi *et al.* (2011) prepared multilayered jute-polyester composite after atmospheric plasma treatment of jute fabrics and found improvements in flexural strength and modulus and interlaminar shear stress. Khan *et al.* (2012) prepared composite by compression molding of four layers of hessian fabrics within five layers of PVC and found the composite containing 40% fiber showed the best performance. An increase in tensile, flexural, and interlaminar shearing strength was observed by Seki *et al.* (2012) in composite made from alkali and oligomer siloxane treated single layer of jute fabric compression molded into two layers of high-density polyethylene (HDPE). Zaman *et al.* (2012) varied the concentration of urethane acrylate oligomer including photoinitiator for pretreating bleached hessian fabric and UV radiated for 24 h for preparing thermoset laminate from five layers of treated jute fabrics through compression molding. They found best results from 70% oligomer treated fabrics. Khan *et al.* (2013) discussed an ecofriendly biocomposite made by compression molding of single layer of jute fabrics sandwiched between poly (ϵ -lactic acid) (PLLA) films. Berhanu *et al.* (2014) sandwiched two layers of jute fabrics between three layers of PP sheets and made thermoplastic composites by hot pressing. They reported significant enhancement of mechanical properties of jute-reinforced composites with the increase of fiber content up to 40% (in weight). Sudha and Thilagavathi (2015) reported a jute-vinylester composite material by compression molding of four layers of alkali treated jute fabrics (16 EPI & 13 PPI; 430 GSM) impregnated with a solution of vinylester resin, catalyst and accelerator. Arju *et al.* (2015) prepared jute reinforced PP composites from single layer of plain (1/1, EPI 10–12 & PPI 10–12) and twill (2/1, EPI 18–20 and PPI 9–10) fabric structures separately sandwiched between two layers of PP sheets and found that the composites having twill structured fabric displayed higher tensile strength than the composites with the plain fabrics. Table 7 shows some examples for manufacturing processes of jute fabric reinforced composite materials.

A work done by Sayem *et al.* (2018) demonstrated the manufacture and analysis of mechanical performance of multilayered jute fabric reinforced thermoplastic composite material. In that work, different layers of jute hessian fabrics having 1/1 plain weave, weight 209 g/m², ends/in. (EPI) 10, and picks/in. (PPI) 9 (Fig. 7), were sandwiched in 0° orientation into several layers of HDPE polymeric sheets and pressed at high temperature and pressure to form composite laminates (Fig. 8). Microscopic findings showed that the placement and orientation of fiber and yarns within the fabric structure remained unchanged in the jute-FRPC. There has been no visible void in the structure. Mechanical performance of the jute-FRPC having a small percentage of fiber content had been found to have improved remarkably when compared with the pure HDPE laminates. The tensile and flexural strength of the laminate composite with optimum number of layers (6-layer makes a weight fraction of 18.50%) were improved by more than 50% (Sayem *et al.*, 2018). The fracture morphology of the jute-FRPC investigated by a scanning electron microscope showed close adhesion of the jute fabrics with the polymer matrices.

Eco-Impact of Nonrenewable Polymer

Nowadays, the biggest end user of plastics worldwide is the packaging sector. It is anticipated that annual production of plastics will be more than 380 million metric tons by 2015 (Geyer *et al.*, 2017). This huge amount of plastics will exhaust approximately 4% petrochemicals as a feedstock; and another 3%–4% is used as energy for manufacturing process. Average per capita consumption of plastics in developed countries is in the range of 80–100 kg/year. In China, annual creation of plastic waste is around 4 million tons of which only 10% are recovered and recycled, 20%–30% are incinerated or landfilled, and the remaining 60%–70% are dumped, discarded, and washed away (Ren, 2003). These plastics are not biodegradable, renewable, and recyclable, thus creating a huge amount of waste, becoming a burden for the environment and as they are dumped in landfills. Therefore, the present usage of plastics is not sustainable and renewable. Biodegradable plastics may work as a promising solution to the

overloaded landfills by decomposing, recycling these natural fiber based plastic materials. **Table 8** shows that packaging is the major source of waste plastics in the UK (Waste Watch, 2003). Other sources such as building and construction, electrical, and electronics are also contributing towards significant portions of waste plastics. Since the majority portion of the packaging materials are fabricated from nonrenewable and nondegradable synthetic plastics, therefore, the top position in landfills is

engaged by the packaging waste. Moreover, there have been several health hazards, particularly in the food division, owing to using synthetic polymers for packaging. This has worked as a driving force to identify and apply biobased and biodegradable alternatives for the packaging sector (Pilla, 2009).

Recently, Bangladesh Jute Mills Corporation (BJMC) has developed a biodegradable and environment friendly jute-polymer based bioplastic bag branded as the Sonali bag (Fig. 9), as an alternative to polythene bag. BJMC is working closely with Futamura Chemical Ltd., a UK-based company, for commercial production of the Sonali bag. This jute-based polymer sheet may work as polymer matrix for making fully biodegradable jute-FRPC.

Conclusions

Jute-FRPCs have many potential applications in automobiles as door panels, seat backs, headliners, dashboards, trunk liners, and parts in railway coaches; in building infrastructure as ceiling, floor, window, wall partition, *etc.*; and as furniture, for example, table, chair, kitchen cabinet, *etc.* The specific modulus of jute fiber is comparable to that of glass fibers (see Table 2), which indicates jute can be used as a substitute of glass fiber in composite manufacturing for certain applications. In 1996, Mercedes used jute to make door panels in its E-class vehicles (John and Thomas, 2008). Alves *et al.* (2010) demonstrated the fabrication of a structural frontal bonnet of off-road vehicles (buggy) with jute/polyester composite as a replacement of glass fibers. It is reported that all major car manufacturers in Germany, namely Daimler Chrysler, Mercedes, Volkswagen, Audi, BMW, Ford, and Opel, are using biocomposites for different applications in cars (John and Thomas, 2008). Jute stands as a potential candidate for all these applications.

Introduction

Theology establishes the fact that the mankind had attempted to cover itself using flexible natural materials since the day of its existence on earth. Archaeological discovery of ancient needles dated back to 26,000–20,000 BCE indicates the craft of sewing was in practice even in the pre-historic time. Further evidences, such as the three-ply cordage dated from 18,000–15,000 BCE found in France and two-ply willow bast net dated to late 8000 BCE found in Finland (Schoeser, 2003), establish that bast fibres, which are collected from the stem of different dicotyledonous plants (Cook, 2001), were among the early natural textile materials used on the earth. Among all bast fibres, flax is known to be first processed industrially to make wearable textiles. According to biblical writings, the spinning and weaving of flax were well advanced even thousands of years ago. The Egyptian mummy cloths aged more than 4500 years old are identified as Linen, the fabric made of flax (Cook, 2001). Following flax, all different natural fibrous materials are used as the only textile materials on the earth until early 1900 when viscose started to appear on the market (Chen, 2015) and then 1940 and 1941 when Nylon and Polyester were introduced to the market respectively (Deopura and Padaki, 2015) and subsequently many other synthetic fibres.

Classification of Textile Materials and Their Applications

According to their geometrical structure and physical appearance, textile materials can be categorised as one of the following types: fibres (including filaments), yarns and threads, fabrics, assembled products (both clothing and non-clothing materials). The basic and starting unit of a textile material is known as a fibre, a hair-like pliable material usually having a length at least hundred times of its diameter. When a fibre comes with an indefinite or endless length, it is termed as a filament. Fibres with limited length, usually short length, are known as “staple fibres” or “short staple fibre” in the textile industry.

Yarn is an intermediate product between fibre and fabric. The International Organisation for Standardization (ISO) considers it as a general term that covers the specific types and structures of single yarn, multiple wound yarn, folded yarn and cabled yarn (ISO 1139, 1973). A single yarn can be made from either discontinuous staple fibres or continuous filaments. For the former case, staple fibres are mechanically twisted together to produce a linear strand capitalising the physical cohesion acts between the fibres to hold each other together. For the latter case, either a monofilament or multifilament yarn is formed from one or more continuous filaments with or without any twist. When two or more single yarns wound together without any twist, they form a multiple wound yarn. However, a folded yarn is formed by twisting together two or more single yarns. Subsequently, if two or more folded yarns (or alternatively folded and single yarns) are twisted together by one or more folding operations, they produce a cabled yarn.

Traditionally fabrics are made from yarns by following two techniques – (1) interlacement of two sets of yarns, or (2) interlocking of loops formed by one set of yarn. The former process is known as weaving and the latter one is as knitting, from which the resultant materials got their names as woven and knitted fabrics respectively. However, fabric like flat assemblies can also be made directly from fibres using bonding technologies like chemical, mechanical and thermal bonding technology etc. As they are neither woven nor knitted, they could be termed as either non-woven or non-knitted, however, the term “non-woven” has become popular and industrially established to refer to those kind of fibrous assemblies. Clothing materials made for our use or sometimes for animal use are assembled products out of mostly fabrics combined with threads and minor non-textiles materials known as fashion accessories. However, assemblies of textile materials with higher percentage of non-textile materials are also made sometimes for industrial applications. Textiles reinforced composite materials are the biggest examples of this type of non-clothing materials.

Fibre Classification

Based on their origin and sources, fibres can be broadly classified as either natural or manufactured (or manmade) fibres (see Fig. 1). Natural fibres comes broadly from three sources: animal, plant and mineral. Synthetic fibres dominate within the group of man-made fibre. A subgroup within the manufactured fibres is natural polymers, which are regenerated from natural resources. They can be considered as “semi-natural” fibres. For example, viscose is manufactured from wood cellulose. In the years 2016 and 2017, the shares of natural fibres in the world production of fibres were 27% and 28% respectively, and regenerated cellulosic fibres belonged to around 6% of the global fibre production in both of the years (see Fig. 2). In the global production of natural fibres, cotton alone takes the share of more than 90% (ToI, 2018).

Table 1 Characteristics of common spinning techniques

<i>Spinning techniques</i>	<i>Twist insertion per minute</i>	<i>Delivery speed (m/min)</i>
Ring	15,000–25,000	20–30
Rotor	80,000–150,000	100–300
Air-jet	150,000–250,000	150–450
Friction	200,000–300,000	150–400

Note: Adapted from Elhawary, I.A., 2015. Fibre to yarn- staple yarn spinning. In: Sinclair, R. (Ed.), Textiles and Fashion, Materials, Design and Technology. United Kingdom: Wood head Publishing, Elsevier, pp. 159–212.

Table 2 Classification of yarns

#	<i>Classes</i>	<i>Examples</i>
1	Staple spun yarns	Carded ring spun, Combed ring spun, Worsted, Semi-worsted, Woollen, Rotor spun, Compact ring-spun, Air-jet spun, Friction spun, Hollow-spindle wrap spun
2	Continuous Filament yarns	Twisted, False twisted, Stuffer-box crimped, Bi-component, Air-jet
2	Composite yarns	Core-spun (filament or staple fibres forming the core and staple as sheath)
4	Novelty yarns	Fancy (Marl, spiral, gimp, diamond, boucle, loop, snarl, knop, slub, fascinated, tape, chainette, chenille, ribbon yarns etc.), Metallic
5	Plied yarns	Two or more yarns twisted together

Note: Adapted from Lawrence, C.A., 2003. Fundamentals of Spun Yarn Technology. Florida: CRC Press. Alagirussamy, R., Das, A., 2015. Conversion of fibre to yarn: An overview. In: Sinclair, R. (Ed.), Textiles and Fashion, Materials, Design and Technology. United Kingdom: Wood head Publishing, Elsevier, pp. 159–212.

All of the natural fibres, except silk, come with limited lengths and they are usually referred as short-staple fibres. Exceptionally, silk is the only natural filament. Man-made fibres are produced as endless filaments, however, they can be cut into staple lengths based on requirement, especially, when they are blended with natural fibres to spin into blended yarns.

Yarn Classification

A yarn is made by inserting twist into a group of fibres that imparts cohesive forces among fibres to make them stick together while forming a linear structure. **Table 1** shows the rate of twist insertion by different spinning techniques used for yarn manufacturing. There are various types of yarns, and they can be grouped into five general classes, such as *staple spun yarns*, *continuous filament yarns*, *composite yarns*, *novelty yarns* and *plied yarns* (see **Table 2**). The common spinning methods used for making staple spun yarns are: Ring, Rotor, Compact, Air-jet, Friction and Wrap spinning. Yarns produced by them are commonly named after them, such as carded ring spun yarn, combed ring spun yarn etc. Worsted and woollen yarns are made from wool using mule-spinning techniques and the steps involved in the processes making them differ from each other. Continuous filaments are mechanically twisted together to produce filament yarns. Silk is an example of natural filament, which is twisted together in different numbers to make yarns depending of the desired thickness and drape of the fabrics to be made out of them. Composite yarns are engineered from more than one component yarns. An example of composite yarn is core-spun yarn, in which filaments or staple fibres form the core and staple fibres surround them as sheath. Novelty yarns are the name of a group that includes fancy and decorative yarns made with regular or irregular design elements and effects, for example slub, flake, spiral ratinè yarns etc. The plied yarns are secondary yarns made from two or more single yarns twisted together.

Fabric Classification

As mentioned earlier, fabrics can be grouped into three categories: woven, knitted and non-woven. The machine used for weaving is commonly known as loom and there are varieties of looms available such as shuttle looms, that include tappet, dobby and jacquard looms, and shuttle-less looms, which include projectile, rapier, water-jet, air jet etc., (Ormerod and Sondhelm, 1995). In weaving technique, two sets of yarns, namely warp and weft, are interlaced in different pattern patterns to produce a two-dimensional surface structure. According to weave design, woven fabrics are commonly classified as *plain*, *twill* and *satin* fabrics as presented in **Fig. 3**. Several derivatives are possible within each of the classes. Even if made with same types of yarns, the fabrics of these three classes will have different textures and different properties, e.g., tensile strength.

Knitted fabrics are broadly categorised as weft or warp knitted fabrics considering the technologies involved in them (see **Fig. 4**). A weft-knitting machine can produce three basic knit designs such as plain, rib and purl (Brackenbury, 1992) and fabrics

Fig. 3 Classification of weave designs.

Fig. 4 Classification of knitted fabrics.

produced are named after the design they contain. Many derivatives are possible within each design type. Warp knitting technique can produce seven different types of fabrics, namely tricot, raschel, ketten raschel, milanese, simplex, crochet and weft-insertion warp (Corbman, 1983).

Non-woven materials are mainly classified into three groups based on the techniques used to lay the fibres together, such as *drylaid*, *wetlaid* and *polymer-laid* (or spunmelt) (Wilson, 2007). Manmade fibres dominate in nonwoven industry by holding over 90% of the share of fibre use. Among the natural fibres, wool can be used alone to make felt which belongs to the category of drylaid non-woven. Other natural fibres such as cotton, jute, kenaf, flex, hemp, coir, sisal, and milkweed etc., have found little nonwoven applications (Mukhopadhyay, 2014; Ma *et al.*, 2011; Ganesan and Karthik, 2016).

Assembled Products and Textile Applications

Application of textile materials can be seen from two major point of views. One is wearable textiles for on-body applications, which include the classic and fashion items that we put on every day or on special occasions. The other one is non-wearable application, which includes home textiles and technical textiles (Fig. 5). Wearable textiles, mostly in the form of a garment, come on to the market in different sizes and styles and in the categories of intimate-wear, outerwear, sportswear, protective gears etc. They are usually made targeting the age and gender of consumers. Home textiles are used for household purposes and they may have functional and/or aesthetic features. Examples of home textiles are bed sheets, pillowcases, blankets, terry towels, tablecloths, carpets, rugs and upholstery.

Fig. 5 The major branches of textiles.

Table 3 Subgroups of technical textiles

#	Subgroup of technical textiles	Areas of application
1	Agrotech	Agriculture, aquaculture, horticulture and forestry
2	Buildtech	Building and construction
3	Clothtech	Technical component of footwear and clothing
4	Geotech	Geotextiles and civil engineering
5	Homotech	Technical component of furniture, household textiles and floorcoverings
6	Indutech	Filtration, conveying, cleaning and other industrial uses
7	Medtech	Hygiene and medical
8	Mobiltech (Transport tech)	Automobiles, shipping, railways and aerospace
9	OekoTech (Ecotech)	Environmental protection
10	Packtech	Packaging
11	Protech	Personal and property protection
12	Sporttech	Sports and leisure

Note: Byrne, C., 2000. Technical textiles market – An overview. In: Harrocks, A.R., Anand, S.C. (Ed.), *Handbook of Technical Textiles*. Cambridge: Woodhead.

Technical textiles use the materials, which are made primarily to capitalise their technical and performance properties rather than their aesthetic or decorative properties (Textile Institute, 1994). Table 3 presents a classification and application areas of technical textiles. Market of technical textiles is rapidly growing as the industrial and academic research activities on the non-traditional application of textiles soared up in the last few decades. In the areas of Buildtech, Homotech and Mobiltech (see Table 3), textile reinforced composite materials have attracted significant attention. However, textile structures from man-made high performance fibres, such as carbon, dominates in the application areas where very high mechanical performance is required, such as aeroplane and car bodies. Natural textile reinforced composite materials are finding their applications in the areas that do not require very high mechanical resistance such as window and doorframes, indoor furniture panels, automotive panels and upholstery, parcel shelves and noise insulating panels etc., (La Mantia and Morreale, 2011).

Natural Renewable Textiles

Textile Materials From Plants

The common polymeric constituent of all plant or vegetable fibres is cellulose, which is a which a polysaccharide consisting of a linear chain of several hundreds to many thousands of $\beta(1 \rightarrow 4)$ linked D-glucose units. However, unlike the glucose in simple sugar, fibre-forming cellulose is not soluble in water due to its huge polymeric size. At elemental level, it is made of carbon (44.4%), hydrogen (6.2%) and oxygen (49.4%), therefore, it is also classified as a carbohydrate. Other than cellulose, vegetable fibres also contain different percentages of hemicellulose, lignin, pectin and wax (see Table 4). Cellulose-rich natural fibres for textile applications can be found from different parts of plants, such as seed, stem and leaf, which are further discussed in the following subsections.

Seed fibres

Table 5 provides a list of common seed fibres, their origins and different applications. Cotton is the most popular and adorable one among all vegetable fibres accounting the lion share of all natural fibres produced worldwide. It is a single cell fibre that

Table 4 Chemical composition of selected natural fibres

Natural fibres	Cellulose (wt%)	Lignin (wt%)	Hemicellulose (wt%)	Pectin (wt%)	Wax (wt%)	Micro-fibrillar/spiral angle (°)	Moisture content (wt%)
Cotton	82.7	0.7–1.6	5.7	–	0.6	14.0	6–8
Jute	61%–71.5%	12%–13%	13.6–20.4	0.2	0.5	8.0	12.6
Flax	71	2.2	18.6–20.6	2.3	1.7	10.0	10.0
Hemp	70.2–74.4	3.7–5.7	17.9–22.4	0.9	0.8	6.2	10.8
Ramie	68.6–76.2	0.6–0.7	13.1–16.7	1.9	0.3	7.5	8.0
Sisal	67–78	8.0–11.0	10.0–14.2	10.0	2.0	20.0	11.0

Table 5 Seed fibres and origin and applications

Fibre type	Fibre name	Plant origin (Common species)	Applications
Seed fibres	Cotton	<i>Gossypium hirsutum</i> , <i>Gossypium barbadense</i> , <i>Gossypium arboreum</i> , <i>Gossypium herbaceum</i>	Different types of garments (shirts, blouses, trousers, jeans etc.), home textiles (sheets, towels, table cloth etc.) and industrial textiles (tarpaulins, bookbinding threads, zipper tapes etc.).
	Java Kapok	<i>Ceiba pentandra</i>	Padding and stuffing for upholstery, lifebelts and other sea-safety equipment.
	Indian Kapok	<i>Bombax malabaricum</i>	
	Coir	<i>Cocos nucifera</i>	Cordage, matting, brushes.
	Milkweed	<i>Asclepias incarnate</i> , <i>Asclepias syriaca</i>	Padding of upholstery, substitute for kapok in lifebuoys
	Balsa	<i>Ochroma pyramidale</i>	Stuffing of mattresses and cushions
	Kumbi	<i>Cochlospermum gossypium</i>	Stuffing of cushion and upholstery
	Silk floss	<i>Chorisia speciosa</i>	Fine fabrics, stuffing for pillow and mattress
	Nepal Trumpet	<i>Beaumontia grandiflora</i>	Coarse rope and stuffing for upholstery
	Calotropis Floss ^a	<i>Calotropis gigantea</i>	Ropes, stuffing for upholstery and pillow
	Cattail fibre	<i>Typha latifolia</i> , <i>Typha augustifolia</i>	Substitute for kapok in life jackets, heat and sound insulation

^aN.B.: Poisonous plant, needs safety precaution while handling.

Note: Cook, J.G., 2001. Handbook of Textile Fibres, vol. I – Natural Fibres. London: Woodhead Publishing Ltd.

evolves from the epidermis or outer skin of a cotton-seed, which may host as many as 20,000 fibres around it. It is an annual crop and grows in the countries, which offer long frost-free time, warm weather, sunshine and adequate moisture. The top cotton producing countries in the world are China, India, United States, Pakistan, Brazil, Uzbekistan, Australia, Turkey, Turkmenistan and Greece (Cotton Australia, n.d). Fibre can be harvested after 5–7 months of planting the seeds, when the ripen seedpods burst to yield a fleecy white cotton boll. These bolls are picked from the plants either manually or mechanically and then passed through a process called “Ginning”, which separates the fibres from seeds and makes them ready for spinning into yarns and threads.

Cotton spinning involves several sub-processes in it, such as blending, opening, cleaning, carding, drawing (stretching), combing, roving and spinning. The earliest and most widely used technique to make cotton yarn is the Ring spinning technique, which can produce both fine and course yarns (Corbman, 1983). Other two techniques, which are relatively new, are Rotor and Friction spinning techniques. These two techniques used to make coarse and bulky yarns. The slub yarns, which are known for their fancy and decorative effects, are usually made by Friction spinning technique (Elhawary, 2015).

Cotton yarns are converted into fabrics by using both weaving and knitting techniques. Cotton fabrics are made using all of basic weaves (plain, twill and satin) and their numerous derivatives. The construction of a woven fabric is usually expressed by the density of warp and weft yarns (industry expressed as Ends per inch (EPI) or Picks per inch (PPI) respectively), the count (i.e., the thickness) of these two types of yarns and weave design that was used for weaving it. A list of few common commercially produced woven cotton fabrics is presented the Table 6.

In case of knitting, weft knitting technique is commonly used to knit cotton yarns into fabric. Industrially cotton knitted fabrics are made by using both circular weft knitting machines and flat knitting machines. Thus, the fabric got its names as circular and flat knitted fabric. The fabrics used for making t-shirts, polo-shirt and similar items are traditionally knitted as circular tubular form. The parts of jumpers and cardigans are usually knitted as flat fabrics.

No other fibre listed in the Table 5 is processed industrially like cotton to produce yarns and fabrics out of them. They are usually processed manually in small scale and home scale facilities.

Bast fibres

Bast fibres grow underneath the bark of dicotyledonous plants. Table 7 presents the list of bast fibres grown and processed for textile applications around the world. Jute is the second most important natural fibre after cotton and mostly produced in Bangladesh, India and China (Quarshie and Carruthers, 2014). Like cotton, the chemical constitution of jute polymer is dominated by cellulose (over

Table 6 List of few common commercially produced woven cotton fabrics

Fabric name	Construction (Warp count x Weft count – EPI x PPI)	Weave Design
20's Sheeting	20's/1 × 20's/1–60 × 60	1/1 Plain
30's Sheeting	30's/1 × 30's/1–68 × 68	1/1 Plain
40's Poplin	40's/1 × 40's/1–132 × 72	1/1 Plain
80's Voile	80's/1 × 80's/1–92 × 88	1/1 Plain
30's Twill	30's/1 × 30's/1–124 × 64	3/1 or 2/1 Twill
8 oz Drill	16's/1 × 12's/1–96 × 56	3/1 Twill
12 oz Bull Denim	7's/1 × 7's/1–68 × 36	3/1 Twill

Table 7 List of bast fibres, their origins and applications

Fibre type	Fibre name	Plant origin (Common species)	Applications
Bast Fibres	Jute	<i>Corchorus capsularis</i> , <i>Corchorus olitorius</i>	Sacks and packing cloths, bags, bailing and bundle cloth, bedding foundation, bonded fabrics, boot and shoe linings, mine brattice cloths and vent tubing, camp bed, cattle beddings, concrete cleavage fabrics, tarpaulins, damp course, cables, plastic reinforcement, filter cloths, fire curtains, furnishings, handbags, mail bags, motor car body linings, concrete reinforcement, roofing felt and upholstery foundation, etc.
	Flax	<i>Linum usitatissimum</i>	Clothing, linen sheets, sail and tent canvas, fishing lines and book-binders' thread.
	Hemp	<i>Cannabis sativa</i>	Sacking and canvas fabrics, ropes and twines
	Sunn/ Sann Hemp	<i>Crotalaria juncea</i>	Cordage, sacking, carpet, rug and fishing nets.
	Kenaf	<i>Hibiscus cannabinus</i>	Ropes, twines, canvas and sacking fabrics and carpets.
	Urena	<i>Urena lobata</i>	Sacking and yarn and fabric as jute alternative.
	Rammie	<i>Boehmeria nivea</i> , <i>Boehmeria tenacissemata</i>	Heavy canvas and packing materials, upholstery and furnishing fabrics, clothing, fishing nets and sewing threads.
	Nettle	<i>Urtica dioica</i> , <i>Urtica pilulifera</i>	Twine and rope, canvas and sail cloth, clothing and furnishing fabrics.

Note: Cook, J.G., 2001. Handbook of Textile Fibres, vol. I – Natural Fibres. London: Woodhead Publishing Ltd. Sayem, A.S.M., Haider, J., Sayeed, M.M.A., 2018. Engineered Material from Natural Fibre for Interior Design Applications, Textile Institute World Conference. United Kingdom: University of Leeds, 23–25 July 2018.

61%–71.5%) (Kabir *et al.*, 2012). However, its chemical composition is specially characterised by the presence of Hemicellulose (13.6%–20.4%) and exceptionally high content of lignin (12%–13%), see Table 4, and therefore, is identified as a lignocellulosic fibre. Unlike cotton, the bast fibres cannot be picked from the plants for use as raw material for making yarns and fabrics. They need to be separated from the bark through a process called “retting”. In traditional retting process, fibre producing plants are immersed in water to allow micro-organisms to act on the bark to dissolve or rot away the surrounding tissues to separate the bundle of fibres from the stem. Nowadays chemical process has also been developed and are being used for retting bast fibres within shorter period of time. Retting process is used for all bast fibres listed in the Table 7 except Ramie, which undergoes different processes called decortication (peeling and beating the bark and bast material) and “degumming” with caustic soda, bleaching powder and dilute acid (Cook, 2001).

Almost, all of the bast fibres are industrially processed to make yarns and fabrics. Based on the physical characteristics of the fibres, their spinning processes differ from each other's. However, these include the basic steps like carding, drawing and twisting. Yarns from these fibres are usually much coarser than cotton yarns. Therefore, the fabrics out of them are also coarser. Usually weaving technique is used to make fabric out of them, except flax, which can also be knitted. Fabric from flax is known as linen and only linen, which has found some uses as clothing material. The fabrics from the rest of the bast fibres mention the Table 7 are used for non-clothing and technical applications.

Bast fibres including jute, flax, hemp, kenaf have been experimented in the last few decades for potential applications as reinforcement in engineered composite materials and have been found very promising. These fibres have good strength and stiffness, whilst being significantly lighter in weight than conventional reinforcements such as glass fibres. Although the tensile strength of these fibres are lower than that of glass fibre, their density is approximately the half, therefore the specific moduli is higher, and tensile moduli is more or less similar, as it can be seen in the Table 8 (Quarshie and Carruthers, 2014; Kabir *et al.*, 2012). On top of that, the environmental drivers like their ability of absorbing atmospheric CO₂ for photosynthesis during production in contrary to synthetic materials and their non-toxic nature, have made them ideal candidates for incorporation into composites for industrial and technical applications that do not require very high mechanical resistance such as window and doorframes, indoor furniture panels, automotive panels and upholstery, parcel shelves and noise insulating panels etc., (La Mantia and Morreale, 2011). The most notable example of industrial use of natural fibre reinforced polymeric composite material is the jute-based thermoplastic door panels produced and commercialised by German automaker Mercedes-Benz in the 90s (La Mantia and Morreale, 2011; Summerscales *et al.*, 2010). Jute has been applied in all possible different forms, such as fibre (Bisaria *et al.*, 2015; Gopinath *et al.*, 2014), sliver (Das and Bhowmick, 2015), yarn (Memon and Nakaib, 2013; Pujari *et al.*, 2015), woven (Sudha and Thilagavathi, 2015; Arju *et al.*, 2015) and knitted (Arju *et al.*, 2015) fabrics as well as non-woven sheets (Karadumana *et al.*, 2014; Sayeed *et al.*, 2014) in composite manufacturing using either thermoplastic (Sayeed *et al.*, 2014) or thermoset

Table 8 Mechanical properties of natural fibres vs. glass fibres

Fibre	Density (g/cm ³)	Tensile modulus (GPa)	Specific modulus (GPa/g/cm ³)	Tensile strength (MPa)	Elongation to failure (%)	Moisture absorption (%)
Flax	1.4	60–80	43–57	500–900	1.2–1.6	7
Hemp	1.48	30–70	20–47	300–800	1.6	8

(Bisaria *et al.*, 2015; Das and Bhowmick, 2015; Pujari *et al.*, 2015) polymeric matrices. Similarly, flax has also got notable applications in composite industry (Quarshie and Carruthers, 2014; Sayem *et al.*, 2018).

Leaf fibres

The leaves of monocotyledonous plants grows fibres in them. Table 9 shows the list of fibres that can be extracted from plant leaves, their origin and applications. Among them, only Sisal and pineapple have got some significant commercial importance and rest of them are produced and processed locally and natively in limited places.

To extract fibre from the leaves, fresh leaves are processed by decorticating machine and then washed with water or sometimes kept for retting to make them ready for spinning (Yu, 2005; Yu and Frank, 2005). Like Jute, Sisal fibres need to be oiled to make them softer and smoother to process to the subsequent stages of yarn manufacturing. Ring spinning technique is used from making sisal yarn (Yu, 2005). The weaving of sisal is similar to that of jute and kenaf. For making rope and twine, pineapple fibre is processed on the jute spinning system. However, for making fine yarns that suitable for fabrics targeting garment manufacturing, pineapple fibres are passed through an enzymatic or chemical degumming process and then spun into yarns using cotton or worsted spinning system (Yu and Frank, 2005).

Textile Materials From Animals

Fibres that come from animal kingdom are based on naturally occurring protein; therefore, they are also known as protein fibres. Fibre forming proteins are composed of different amino acids and can be of very complex to simple structures. Common animal

fibres are silk from different insects, wool from sheep and hairs from different camel and goat like animals. Silk is the strongest among all natural fibres (Corbman, 1983; Cook, 2001).

Silk fibre

The larvae of the caterpillar of the species *Bombyx mori*, known as silkworm, produces liquid protein which solidifies in contact with air when excreted through natural spinneret (caterpillar's jaw). At a certain stage of its life cycle, a silkworm produces a cocoon by wrapping itself with its own protein fibres. If left undisturbed a cocoon develops into a moth within two week. However, in sericulture industry silk worms are reared just to produce the cocoons from which silk fibres are collected. Silkworm larvae are fed on mulberry leaves and hatched for around 35 days before they become ready for reeling, the process of unwinding of silk filaments from cocoons. It requires the cocoons to be immersed within hot and cold water step by step to soften the natural gummy substance, *sericin*, that holds together the filament strands. Reeled silk is then transformed into filament yarns by a process called throwing (an alternative term of twisting used in the silk industry). Fabrics from silk yarn are usually made by following weaving technique. Silk fabrics are usually soft, lighter in weight than fabrics from any other natural fibres and have a luxurious appearance, and they are popular for clothing applications.

Wool fibre

Wool fibre is formed by a complex protein called "keratin" that grows from the follicle in the skin of sheep. Including all breeds and cross-breeds of sheep found around the world, there over 200 distinct grades of sheep from which wool can be collected (Corbman, 1983). The best quality wool are known as merino wool. It comes from a breed of sheep known as merino which includes the varieties of Ohio Merino, Australian Silesian and French Rambouillet. Sheep are normally shorn of their fleece every year. Raw wool contains a lot of dust and dirt, natural grease and dried perspiration "suint". Therefore, it needs to be scoured with warm water containing detergent before spinning into yarns. Woollen and worsted are two different types of yarns produced from wool. Woollen yarns are thicker, fuller and looser than the worsted yarn. The fibre preparation and spinning processes also vary for these two type of yarns. Both weaving and knitting technology are used to make fabrics out of woollen and worsted yarns. Wool fabric provides warmth to the users; therefore, varieties of winter clothing are made from it.

Other hair fibres and feather

Different species of camels and goats are sources of protein fibres that can be used as textile materials. However they are not usually nurtured in large scale like sheep to produce fibres. Two-humped Bactrian camel is known for its fine hair fibres. Other camel like animals from which hair fibres are collected are Llama, Alpaca, Vicuna and Guanaco. Cashmere wool and mohair fibres come from Cashmere and Angora goats respectively. Hairs from Angora rabbit and Qiviut ox are also known for their textile uses. Fillers for cushions, pillows quilted outerwear are also made from cow hair, horse hair, down and feathers from ducks and geese.

Textile Materials From Minerals

The natural fibrous materials come from minerals formed in varieties of rock found in Italy, South America and Canada are known as asbestos. Chemically it is a form of silicate of magnesium and calcium containing iron, aluminium and other minerals. Asbestos can be spun into yarn, and in the past, it found applications in the firefighting suits and different fire resistant materials like theatre curtains, draperies etc., due to its fireproof property. However, the use of asbestos is banned in many countries today as it was found hazardous to health.

Comparison of Properties among the Natural Fibres

This section compares density, stiffness, strength and energy storage properties of the bio-based natural fibres both from plant and animal origin using Ashby charts (see Figs. 6–8) derived from CES EduPack Software (Ashby, 2007). Other than direct natural fibres, three other natural materials (wood, bamboo and palm) are also considered in the chart for reference purpose. The only mineral fibre, asbestos, is presented in the graphs but not considered in the discussions as it is currently not being used for technical application. It should be noted that their property values are given for bulk material as their corresponding fibre property values are not available in the database. Some popular man-made fibres such as Kevlar, glass, steel, carbon, polyethylene were also plotted to compare their properties with the natural fibres. Additional man-made materials in the bulk form such as polyester, nylon and rubber were also plotted.

Stiffness and density

Higher stiffness and lower density are important properties of fibres needed for textile applications. Fig. 6 presents the relationship between stiffness defined by Young's modulus and density of different natural and man-made fibres. Each bubble represents an individual material with its ranges of Young's modulus and density. The large envelopes enclose a group of materials for a particular class such as natural fibre, natural material, elastomer, plastic and man-made fibres. The chart reveals that natural materials can cover a wide range of density and Young's moduli similar to the engineering materials currently being used (Shah, 2014). The specific values of densities and Young's moduli for individual materials are listed in Tables 10 and 11. In

Fig. 6 A comparison of stiffness vs density between natural and some selected man-made fibres.

Fig. 7 A comparison of specific strength vs specific stiffness between natural and some selected man-made fibres.

Fig. 8 The maximum capacity of elastic energy storage with density for the natural fibres and some selected man-made fibres.

general, the densities of bio-based fibres are clustered in a narrow range from 1.14 kg/m^3 (coir) to 1.60 kg/m^3 (cotton). Among the man-made fibres, only Kevlar and polyethylene fibres have densities falling within the same range for the natural fibres. Due to low density and weight of natural fibres is also very low and this makes them attractive for the textile applications. In general, animal-based fibres are lighter than the plant based fibres.

On the other hand, the Young's modulus of bio-based fibres varies over a long range from 0.15 GPa (Silk-Spider viscid silk) to 73.5 GPa (hemp). Ramie has even better strength than some of the strongest man-made fibres such as Kevlar and glass fibres. Other bast fibres such as kenaf, jute, flax and hemp have similar strength compared to that of Kevlar. It is interesting to note that fibres from animal sources display lower strength than the plant based fibres.

Strength and stiffness

In general, the textile fibres should have both high axial stiffness and strength that determines their performance in application. In many cases, nature has already accommodated those properties in the bio-based fibres. Specific tensile strength (strength/density) and specific stiffness (stiffness/density) of different fibres are plotted and presented in Fig. 7. In terms of both specific strength and stiffness, some of the bast fibres such as ramie, flax, hemp, kenaf and jute can perform equal or better than steel. However, few man-made fibres such as Kevlar, carbon, glass and polyethylene perform far better than the bio-based fibres. Among the plant-based fibres, flax displays the best performance under tensile loading condition. However, the performance of animal-based fibres are not quite as good as the bast fibres.

Elastic energy and density

Fibres, like a rubber band, can store energy when stretched. Elastic energy storage is a measure of the energy required to stretch a fibre. The maximum energy storage is measured by the quantity $\sigma_{ts}^2/2E$ per unit volume or $\sigma_{ts}^2/2\rho E$ per unit weight, where σ_{ts} is tensile strength, E is Young's modulus and ρ is density. A higher energy storage value for a material indicates that the material has the ability to act like a spring, which can help in absorbing an impact load. Fig. 8 presents a chart of energy storage and density (Ashby, 2007). Among the natural materials, silk has the capacity of storing highest elastic energy even better than rubber or steel. A number of other plant-based natural fibres such as flax, cotton, sisal, hemp, jute and ramie also have either equal or better ability to store elastic energy than some of the polymeric materials such as nylon and polyester.

Semi-Natural Renewable Textiles

As presented in the Fig. 1 in the Section "Fibre Classification", a portion of man-made fibres comes from natural polymers extracted from pure natural sources existing in different physical forms other than in fibre form. These include alginate, rubber,

Table 10 Range of densities for different natural fibres and materials with their man-made counterparts

Material type	Name	Density (kg/m ³)
Polymer and elastomer	Polyethylene fibre	965–975
Seed fibre	Coir	1.14e3–1.2e3
Bast fibre	Kenaf	1.19e3–1.2e3
Animal fibre	Wool	1.2e3–1.32e3
	Silk (Spider drag-line silk)	1.26e3–1.35e3
	Silk (Spider viscid silk)	1.26e3–1.35e3
	Silk	1.26e3–1.35e3
	Human hair	1.3e3–1.4e3
Bast fibre	Jute	1.3e3–1.5e3
Bast fibre	Flax	1.4e3–1.5e3
Man-made fibre	Kevlar 29	1.43e3–1.45e3
Leaf fibre	Sisal	1.45e3–1.5e3
Bast fibre	Ramie	1.45e3–1.55e3
Bast fibre	Hemp	1.48e3–1.5e3
Seed fibre	Cotton	1.5e3–1.6e3
Man-made fibre	Carbon fibre	1.8e3–1.85e3
	Glass, C grade	2.49e3–2.5e3
	Steel wire	7.85e3–7.9e3

Table 11 Range of Young's modulli for different natural fibres and materials with their man-made counterparts

Material type	Name	Young's modulus (GPa)
Animal fibre	Silk (Spider viscid silk)	0.15–0.25
	Human hair	2.3–3.6
	Wool	3.9–5.2
Seed fibre	Coir	4.0–9.0
	Cotton	5.5–28
Animal fibre	Silk (Spider drag-line silk)	9.0–11.0
	Silk	9.3–15
Leaf fibre	Sisal	9.4–22
Bast fibre	Jute	13–60
	Kenaf	14–53
	Flax	27.6–100
	Ramie	61.4–128
	Kevlar 29	62–80
Man-made fibre	Glass, C grade	66–70
	Hemp	66.5–73.5
Bast fibre	Polyethylene fibre	120–170
Man-made fibre	Steel wire	200–210
	Carbon fibre	370–390

regenerated protein, regenerated cellulose and cellulose ester. The regenerated cellulosic filament viscose, also known as rayon, is the leading semi-natural fibre that has got commercial importance. Lyocell is another regenerated cellulosic fibre, which follows an eco-friendly production process and possesses improved fibre properties compared to viscose.

Sustainability Analysis of Bio-Based Fibres

Product Life Cycle (PLC) of Natural Fibres

A product life cycle of natural fibres for textile application is presented in Fig. 9. Most of the bio-based fibres come from plants, which absorb environmentally harmful carbon dioxide (CO₂) and releases lifesaving oxygen (O₂) during plant life cycle. Thus, CO₂ footprint from the plant-based natural fibres would be much less at the source compared to the man-made fibres. After fibres are extracted from natural sources, few additives are often added to them to improve their performance in subsequent processes to convert them into value-added intermediates like yarns and fabrics. Finally, commercial products are made from them through design, manufacturing, assembly and packaging operations. After consumer use, a number of options available for the natural textiles materials that make them attractive from sustainability point of view. The old clothes in good condition can be donated or sold to the consumers in developing countries to

Fig. 9 Product life cycle of natural fibres.

expand their life cycle. The used textiles can be recycled by extracting the fibres out of them to feed them back in the product life cycle. The used products in good condition can be also be used for making other products through disassembly, redesigning and remanufacturing. The materials that are not suitable for further recycling, can be disposed to the landfills. Through natural degradation in course of time, the disposed materials get mixed with soil and become integral part of mother earth.

CO₂ Footprint and Embodied Energy for Natural Fibres

During primary material production, CO₂ footprint and embodied energy are the two indicators most frequently used to measure the environmental impact. CO₂ footprints of natural fibres and some synthetic fibres are presented in Fig. 10. It is very clear that CO₂ footprint of natural fibres during primary production is lower than that of the manmade fibres such as glass, carbon, Kevlar and polymeric fibres. Lower CO₂ footprint from the natural fibres is not the only benefit but the fibre-producing plants also absorb CO₂ from the nature and release oxygen. This creates a positive impact from sustainability point of view. In addition, the bio-based fibres are naturally biodegradable and benign to eco-system. Unlike synthetic fibre, plant-based fibres do not produce any toxic emission during production, although, raising animals for fibre collection can some emit greenhouse gases. In general, the price of the bio-based fibres are much less than the price of their synthetic counterparts. In general, the man-made fibres are more expensive than the natural fibres but steel and glass fibre prices are somewhat closer to the prices of the natural fibres. Jute and kenaf are the cheapest among the bast fibres. An almost identical chart can also be obtained for embodied energy versus price as shown in Fig. 11.

Research and Innovation

Research is being carried out to explore non-traditional natural resources as a source of textile materials. Few examples are presented in this section.

Fig. 10 CO₂ footprint for different fibres with prices.

Fig. 11 CO₂ footprint for different fibres with prices.

Fig. 12 Knitted swatch from alginate yarns. Reproduced from Preuss, S., 2018. Sustainable textile innovations: Bio yarn made from kelp fibres. Available at: <https://fashionunited.uk/news/business/sustainable-textile-innovations-bio-yarn-made-from-kelp-fibres/2018032628811> (accessed 11.12.18).

Protein Fibre From Yeast

Recent developments in genetic engineering have enabled researchers to impregnate protein producing DNA into yeast to produce protein in laboratory (Vendrely and Scheibel, 2007). A company called “Bolt Threads” (see “Relevant Websites section”) has reported the production of fibre and yarn for textile uses from protein achieved through fermentation of genetically modified yeast in the presence of sugar and water (Bolt, n.d.). They extract the liquid protein from yeast and extrude it through spinneret to get filaments in the same way acrylic and viscose filaments are extruded.

Alginate Fibre From Algae

Some species of seaweeds from the orders Laminariales and Fucales, commonly known as kelps and fucoids, respectively, are a great source of alginate (Peteiro, 2018). This can be chemically extracted as sodium alginate solution to convert to fibres (FAO, n.d.; Quin, 2008). A biomaterials research company AlgiKnit (see “Relevant Websites section”) has reported a compostable yarn from kelp that can be formed into wearable textiles. It extracts alginate from kelp and combines it with other renewable biopolymers to produce yarn, which is strong enough and stretchable enough to be knitted by hand or by machine to be used in textile manufacturing (see Fig. 12). The fabric from this type yarn can also be dyed with natural pigments.

Lotus Fibre

A Cambodian company Samalota Lotus Textiles (See Relevant Websites Section) is promoting the extraction of natural fibre from lotus stems to make woven fabric out of this (Preuss, 2017). Lotus plants grow in abundance in many Asian wetlands. The lotus flower, according to Buddhist teaching, is a symbol of inner-determination and spirituality. Lotus clothes were worn by Buddhist monks centuries ago for this spiritual value. After years of oblivion, this lost handicraft has now been brought back to life by this Cambodian company. The extraction of fibre from lotus stem is quite time-consuming but the fibres produce luxurious fabrics that feel like a combination of silk and raw linen. After harvesting the lotus stems from lakes, the artisans slice the end of the stems and pull out the long, thin fibres from the centre. The long strand of fibre are then washed and hung to dry and finally handwoven on looms into fabric.

Conclusion and Future Trend

As an industry, textile is one of the largest industries globally and one of the most polluting ones (European Commission, 2013). At the same time, production and processing of textile materials is very energy consuming and resource hungry. Although at the production stage, most pollution may occur from the production of manmade fibres, natural fibres are also not free from the guilt. Growing cottons require a high level of water and pesticide consumptions. Examples of serious impact of toxic chemical used cotton farming include the reports of death of a US cotton farmer from a brain tumour and serious birth defects in Indian cotton farmers’ children (Parry, 2018). The evolve of pest-resistant genetically modified cotton varieties also may lead to problems further down the line, such as the emergence of “superweeds” which are resistant to standard pesticides and will require more toxic

pesticides to control them, which will be eventually more harmful to surrounding livestock and humans (Parry, 2018). Although research and initiatives are being undertaken to develop new sources of renewable textiles, it is also important to undertake more and more research on fixing the hundreds of years old pollution-prone techniques of producing and processing textiles materials.

In order to reduce the ecological impact of textile industry, it is important to make use of more and more bio-based renewable and biodegradable fibres as a building block of textile products. However, the key challenge is to first find out natural fibres, which have critical performance properties same as the man-made fibres as it is not just enough for the natural fibres having only low CO₂ footprint. The bio-based additives are equally important to introduce in the processing of the natural fibres to further lowering the eco-impact. Consumers usually feel good about their clothing made of bio-based fabrics and are even ready to pay more to help create a sustainable world. However, building awareness among consumers is still an important issue to encourage the increased use of bio-based textiles avoiding synthetic textiles.

Introduction

The blanket term *biomaterials* is usually used to mean biological, biomedical, and bioderived materials (Ashby and Pereira-Medrano, 2015). Natural materials that are produced directly by biological systems (such as skin, bone, wood, shell, hair, etc.) are biological materials. Materials like paper, plywood, twine, and rope, which are synthesized from natural biological materials, are classified as bioderived materials. In this paper, the term *biobased materials* is used to cover both biological and bioderived materials. This article does not cover biomedical materials, which are biocompatible, but nonbiomaterials like bioglass, alumina biceramics, titanium, silver amalgam etc., and bioinspired materials and structures that mimic nature and biological materials.

Three-dimensional (3D) printing is a technique of physical prototyping from virtual CAD models through layer-by-layer deposition of materials. It is also known as additive manufacturing, solid freeform fabrication, and layered manufacturing (Bose *et al.*, 2018). Until recently, 3D printing was mainly limited to model making and one-off product manufacturing for specialized applications such as body part replacement in biomedical field. One of the key reasons for the limited application can be attributed to the lack of available materials in the form suitable for 3D printing. Polymers have been widely used as the primary material for many years. However, more recently materials all major families are becoming popular in 3D printing industry due to a number of reasons such as advancement in 3D printing technologies, advancement in materials processing in suitable form, worldwide push towards digital manufacturing, etc. Fig. 1 presents some of the popular materials used in 3D printing. The technology has become very popular nowadays and both home-scale and industrial scale 3D-printers are now available on the market for a variety of application areas (Fig. 2). There has also been a great interest of 3D printing using biobased raw materials from industry and academia in the recent years. This article provides an overview of the development of biobased materials for 3D printing and its research and future application prospects.

Biobased Materials

A General Overview

Proteins, polysaccharides, and minerals are the basic structural building blocks of nature. Proteins are fundamental components of all living cells and they are complex organic macromolecules made from the basic elements hydrogen, oxygen, nitrogen, and sulfur. Polysaccharides are polymers of monosaccharides such as glucose, fructose, and galactose. Polysaccharides that serve as energy storage in plants and animals are starch and glycogen. Common examples of structural polysaccharides are cellulose and chitin. Cellulose is abundantly found in plants and is said to be the most abundant organic molecule on Earth. Chitin has a similar

structure to cellulose, but differentiated by its nitrogen-containing side branches. It is found in arthropod exoskeletons and in the cell walls of some fungi.

Complex of covalently linked protein and polysaccharides, such as glycoproteins and proteoglycans, are also found in biological systems. Collagen is a glycoprotein that serves as natural structural molecule and antibodies. Other important natural materials that are part of biological systems are minerals in form of ceramics such as calcite, aragonite, hydroxyapatite (HA), and biosilica. Living tissues incorporated with these minerals are known as mineralized tissues.

Biobased materials exist in a variety of forms in nature such as soft tissues, mineralized hard tissues, wood and wood-like materials, and natural fibers (Ashby and Pereira-Medrano, 2015). There are two broad groups of soft tissues found in animals – active (muscle) and passive (connective tissues). Muscles are predominantly protein based and connective tissues such as ligament, tendon, and cartilage are predominantly acellular composite materials made of proteins, polysaccharides, and glycoproteins. Although included in this group, the keratinized tissues such as hair, horn, hoof, and the shells of turtles and tortoises are much stiffer and stronger than other tissues.

The mineralized hard tissues include dentine and enamel (of teeth and tusk), bone, antler, shell (of exoskeleton), and corals. These are living tissues combined with minerals. All wood and wood-like materials are made of cellulose and their examples include tree-wood, palm wood, bamboo, cork, and nutshells. Other forms of biobased materials are natural fibers that are also abundantly found both in the plant and animal kingdoms. Further details of natural fibers can be found in Sayem and Haider (2019).

Bioplastics

The organization called European Bioplastics defines bioplastics as the plastic materials that either biobased or biodegradable, or both. According to this definition, the term covers the following three groups: Biodegradable biobased, biodegradable fossil-based, and nonbiodegradable biobased bioplastics (Norwegian Environment Agency, 2018), as can be seen in Table 1.

Hydrogel

Another very promising and well-researched biopolymer is hydrogel. Hydrogels are 3D polymer gel networks capable of holding nutrition within the water and extruding them in a controlled and precise manner (Skardal and Atala, 2015). They have been used in regeneration medicine such as drug delivery and tissue engineering because of the ability to produce them with a tunable elastic modulus that can mimic soft tissue (Seliktar, 2012). Basically, hydrogel can be made of natural polymer, synthetic polymer, or a combination of the natural and the synthetic polymer (Kirchmayer *et al.*, 2015). In contrast to the hydrogel made of natural polymer, hydrogel from synthetic polymer suffers from nonbiocompatibility, poor cellular adhesion, and limited or no biodegradability (Murphy and Atala, 2014; Skardal and Atala, 2015). However, they have advantages of tunable molecular weight, high mechanical property, and other limitations can be avoided with proper programming in processing and material selection

Table 1 Three groups of bioplastics

#	Groups of bioplastics	Examples
1	Biodegradable biobased	Poly(lactic Acid), Poly(hydroxyalkanoates), starch blends (including Mater-Bi), Poly(butylene Succinate (Adipate) [PBS(A)]
2	Biodegradable fossil-based	Poly(butylene adipate terephthalate, [PBS(A)], Polycaprolactone, Poly(vinyl Alcohol)
3	Nonbiodegradable biobased	Biopoly(ethylene Terephthalate), Biopoly(ethylene), Poly(ethylene furanoate), BioPoly(propylene), Biopoly(amide (Nylons/bioPA), Poly(trimethylene terephthalate)

Note: Norwegian Environment Agency, 2018. BioBased and biodegradable plastics. An assessment of the value chain for biobased and biodegradable plastics in Norway. Available at: <https://www.miljodirektoratet.no/Documents/publikasjoner/M1206/M1206.pdf> (accessed 26.02.19).

Fig. 3 Schematic depiction of 3D bioprinting methods: Extrusion-based methods such as fused deposition modeling and direct ink writing, inkjet printing, stereolithography. Reprinted with permission from Guvendiren, M., Molde, J., Soares, R.M.D., Kohn, J., 2016. Designing biomaterials for 3D printing. *ACS Biomaterials Science and Engineering* 2 (10), 1679–1693. doi:10.1021/acsbiomaterials.6b00121. Copyright (2016) American Chemical Society.

(Murphy and Atala, 2014; Kirchmayer *et al.*, 2015). Poly(ethylene glycol) (PEG) is ethylene oxide with ether functional group and is most commonly used in 3D bioprinting (Kirchmayer *et al.*, 2015). An acrylate chemical modification of PEG is poly(ethylene glycol) diacrylate (PEGDA), which facilitates cell encapsulation more efficiently than raw PEG (Skardal and Atala, 2015). The monomer covalently bonds to create the polymer, which is not biodegradable, but biocompatible (Kirchmayer *et al.*, 2015).

3D Printing Technology

The basic components of 3D printing technology are (1) hardware, the physical constituents of the machine itself; (2) software to develop and process 3D design and to convert it into machine-readable instructions; and (3) the raw materials used as ink for producing 3D objects. The physical properties of 3D printed objects depend on the material selection, printing principles, and printing process parameters (Guvendiren *et al.*, 2016). The 3D printing process is very robust and it can be tuned to utilize numerous functional materials including biobased materials in the form of ink for printing complicated 3D structure like scaffold for cell growth, implantable tissues, etc. (Skardal and Atala, 2015). A number of 3D printing methods are shown in Fig. 3, which include extrusion-based 3D printing methods, inkjet printing, stereolithography (SLA), and laser-induced forward transfer method (Skardal and Atala, 2015; Guvendiren *et al.*, 2016; Jammalamadaka and Tappa, 2018). Selection of a printing method from any of these depends on the fluid (ink) flow properties and the desired structural resolution of the printing object.

Extrusion-based methods such as fused deposition modeling (FDM) is based on the simple idea that a filamentary thermoplastic material is forced through a heated nozzle that simultaneously melts the material and follows a predefined path determined by a computer model to build up a 3D object layer-by-layer in the vertical direction. The extruded material solidifies with time that can be detached from the printing bed when the printing process is fully executed (Guvendiren *et al.*, 2016). The FDM process is feasible for printing with biomaterials that are thermoplastic in nature, but not suitable for other types of temperature sensitive biomaterials.

On the other hand, direct ink writing (DIW) method uses a thixotropic fluid (as ink), which is formulated with the proper mixture of a fluid loaded with filler particles and the polymeric binder (Guo *et al.*, 2013). The ink material is extruded through a nozzle that can travel in X, Y, and Z directions similar to FDM method. The printed material can be solidified via thermal or light energy.

The popular inkjet printing process can also be tuned to use functional ink and develop high-resolution 3D object by layer-by-layer deposition of droplets on demand (Skardal *et al.*, 2012). Unlike, FDM, DIW, and inkjet, SLA can print 3D objects from the bottom up by shining UV light pattern in the resin bath. The light can solidify the resin during its travel (Soman *et al.*, 2013). However, this process is restricted for all the other types of functional materials, which are not photocurable. Further details about the advancement in 3D printing technologies can be found in the recent literature (Wijk and Wijk, 2015; Ngo *et al.*, 2018; Liu *et al.*, 2019; Tofail *et al.*, 2018).

Carbon Neutral Manufacturing With 3D Printing of Biobased Materials

Petroleum based polymer materials are being used in a wide variety of applications. However, from the sustainability point of view, they are not the most attractive options due to a number of reasons such as CO₂ generation during production, gradual depletion of limited feedstocks, landfill with nonbiodegradable polymers, and CO₂ generation during combustion. Therefore, biobased polymers from plant cellulose open up the opportunity to overcome those barriers and to create a sustainable planet. Traditional manufacturing techniques such as machining work on the subtractive principle where material is removed to create a shape, meaning a lot of waste. On the other hand, 3D printing works on additive principle and is considered as a waste-free process. Therefore, the combination of biobased materials and 3D printing can create the opportunity to realize carbon neutral manufacturing in the near future. In this concept, the products made out of the biobased polymers can be recycled to manufacture new products or be fully degradable upon landfilling (Fig. 4).

A group of Russian researchers developed biomass-derived poly(ethylene-2,5-furandicarboxylate) and made objects via 3D printing, which showed better performance than commonly available materials such as acrylonitrile butadiene styrene (Kuchero *et al.*, 2017). Several successive recycling of the material in 3D printing did not show any significant degradation of performance.

The bases of electric lamps were manufactured by 3D printing from electrically conductive biobased plastic partially from renewable resources and graphite (Villanueva *et al.*, 2018). Filament was made by extrusion technique and used as a raw material for manufacturing the lamp base by FDM. Sustainability analysis shows that 3D printed biobased lamps can reduce environmental impact such as CO₂ footprint when compared with the lamps made of glass and metallic materials and opens up the opportunity to replace these high carbon traditional materials. The biobased materials also can reduce the weight of the lamp by 55%, which has other environmental benefits during transportation such as lower fuel consumption and emission.

It is a big challenge to protect complex, sensitive, or fragile parts during transportation using standard packaging as in most of the cases their designs are not suitable to match the shape of the part. This demands adaptive packaging design and manufacturing, which could be very costly and time consuming. 3D printing of adapted packaging using renewable biobased waste materials such as wood flour, rice husk, or miscanthus fiber has been trialed to overcome the challenges in packaging (Zeidler *et al.*, 2018). The

Fig. 4 Carbon neutral cycle from 3D printed biobased product. Modified from Wiley Newsroom, 2017. From cellulose to 3D objects: 3D printing with a biobased polymer for CO₂-neutral manufacturing. Fig. 5 General requirements for 3D printing with biobased materials. Modified from Liu, J., Sun, L., Xu, W., *et al.*, 2019. Current advances and future perspectives of 3D printing natural-derived biopolymers. *Carbohydrate Polymers* 207 (1), 297–316.

combination of biobased material and 3D printing creates an attractive scenario for carbon neutral manufacturing of sustainable and biodegradable packaging through re or upcycling of biobased waste materials. 3D printing can also conform to the ability of making complex adaptive packaging just-in-time.

Biobased Materials Requirements for 3D Printing

To make commercially viable sustainable products by 3D printing using biobased raw materials, certain criteria must be complied with both from the materials and processing point of views as shown in [Fig. 5](#). [Liu *et al.* \(2019\)](#) discussed key characteristics that the biobased materials should have to be used as raw materials in 3D printing for few specific applications such as biomedical, food, and textile products. The following subsections highlight the requirements from biobased materials for specific application areas relevant to 3D printing.

Medical and Pharmaceutical Applications

The ample use of biobased polymers in 3D printing technology opens up many windows and extends the existing possibilities in biomedical engineering as it is easy and simple to process them and the cost involved is low ([Skardal and Atala, 2015](#); [Guvendiren *et al.*, 2016](#); [Jammalamadaka and Tappa, 2018](#)). The areas of biomedical and pharmaceutical research where 3D printing is being applied are (1) fabrication of tissue and organ including customization of prostheses, implants and anatomical models; and (2) personalized drug dosage delivery system and drug screening ([Derby, 2012](#); [Melchels *et al.*, 2012](#); [Murphy and Atala, 2014](#); [Ventola, 2014](#); [Zhang *et al.*, 2015](#)). The 3D printing techniques, which are found suitable for medical and pharmaceutical applications, are extrusion-based printing technique, inkjet-based technique, fused particle based technique, and light-assisted 3D technique. These techniques will demand different mechanical and chemical properties from raw materials related to processing and printing performances. However, the biobased materials should meet the strict requirements in terms of printability, biocompatibility, degradability (degradation into safe by-products) and good degradation kinetics, ability of tissue biomimicry and appropriate mechanical properties in general for medical, and pharmaceutical applications ([An *et al.*, 2015](#); [Derby, 2012](#); [Murphy and Atala, 2014](#)).

Food Production

The 3D printing techniques that have found application in food fabrication are extrusion-based technique, selective sintering technique with laser or hot air, binder jetting, and inkjet printing technique. These different techniques will demand different physical, chemical, rheological, structural, and mechanical features from the raw materials they use. However, the biobased materials for use in 3D printing of food should be primarily edible, nontoxic, rigid, and stiff enough to support their own weight and resistant to post-processing such as baking, cooking, and frying. The biobased materials that have been used in 3D food printing so far are cellulose, hemicellulose, pectin, starch, alginate, agarose, and chitosan due to their favorable features like nontoxicity, edibility, high abundancy, bioactivity, and compatibility with foods ([Alec, 2016](#); [Godoi *et al.*, 2016](#); [Lille *et al.*, 2018](#)).

Textile Application

3D printing technique has yet to reach sufficient efficiency to reproduce true textile structures with appropriate fineness, flexibility, and drape characteristics. However, 3D printing has been found effective to build different small components on textile surfaces. FDM and SLS (selective laser sintering) techniques have been applied for 3D printing associated to textile applications (Beecroft, 2016; Tenhunen *et al.*, 2018). Among the biobased materials, PLA shows potential for this field. Among the key requirements from biobased raw materials, the most notable ones are flexibility, drapability, and washability, when it comes to any textile application.

Current Research and Challenges

3D printing With Bioplastics

Poly(lactic acid) (PLA) is a widely used biopolymer to print different tissues, including liver, kidney, and cardiac tissues, which forms the organs that are transplanted most (Serra *et al.*, 2013). Transformation of PLA into filament is very easy and can be printed in extrusion printing methods. However, the long-term biodegradability and the formation of acetic acid during degradation lead to tissue death and make this polymer unsuitable. To solve this problem, PLA is combined with ceramics and forms a composite, which improves the mechanical properties and reduce the formation of the localized acidic environment (Serra *et al.*, 2013). PLA bioplastics are mainly printed by FDM printing methods to fabricate packaging devices (Serra *et al.*, 2013; An *et al.*, 2015). Some other polymers such as poly(propylene fumarate), poly(D, L-lactide) are successfully used in SLA method as biodegradable and photocrosslinkable polymer (Guvendiren *et al.*, 2016).

Often biobased materials are mixed with nonbiobased materials to improve the performance of 3D printed parts/products. For example, ceramics materials are largely used in 3D bioprinting of bone and tissue engineering. Due to their osteoconductive and osteoinductive nature, metal and inorganic salt of calcium and phosphates are potentially used to print scaffolds for bone and dental tissue engineering. In this case, pressure extrusion 3D printing method is a potential candidate since this process does not require high temperature melting process during printing. β -tricalcium phosphate (β -TCP), α -tricalcium phosphate, HA, bi-phasic calcium phosphate (BCP a mixture of β -TCP and HA), calcium sulfate, calcium phosphate cement, and titanium are potentially used as biomaterial for 3D printing (Tarafer and Bose, 2014; Chia and Wu, 2015; Sa *et al.*, 2018). However, the scaffolds produced using the ceramic materials are brittle in nature. To improve cytocompatibility, vascularization, and mechanical properties, some polymeric biomaterials such as chitosan, polycaprolactone, PLA, poly L-lactide-glycolic acid, and PEGDA are added to the salts of calcium and phosphates (Chia and Wu, 2015). Some examples of 3D printing in the biomedical field are presented in Fig. 6.

3D Printing With Hydrogel

Hydrogel made of the natural polymer has the disadvantage of carrying pathogens from its sourcing body and inconsistency in structure and molecular weight as they are extracted from the various living body (Collier and Segura, 2011). However, they show the most excellent biocompatibility and degradability as they have a natural attachment to interact with cell (Kirchmayer *et al.*, 2015). The hydrogels made of a natural polymer such as alginate, collagen, fibrin, hyaluronic acid retain their innate biological activity. As a result, they do not require any biological preprogramming (Murphy and Atala, 2014). Inkjet printing, photopolymerization, and extrusion are some efficient methods of hydrogel printing (Skardal and Atala, 2015). The printed polymer ink or solution is stabilized by either physical bonding or chemical bonding (Guvendiren *et al.*, 2016). Physical bonding such as electrostatic bonding, photocuring, and curing avoid the potentiality of toxic chemicals, whereas chemical bonding evolves the polymer to be resistant to mechanical stress (Guvendiren *et al.*, 2016).

Collagen is a proteinaceous biopolymer that acts as reinforcement in scaffolds in gel form under neutral pH and crosslinking agent, which is dissolved in acetic solution. This pH-sensitive property is used for 3D printing where gelation occurs by physical bonding and crosslinking as well (Wang *et al.*, 2015). However, this acidic requirement creates a deadly environment for the survival of cells. Glutaraldehyde is a potential crosslinker for the gel state formation (Rajaram and Chu, 1990).

Alginate is a polysaccharide used for cell encapsulation in microsphere. It is also more inexpensive than collagen because it is derived from seaweed and algae (Skardal and Atala, 2015; Kirchmayer *et al.*, 2015). This hydrogel is formed by electrostatic interaction between negatively charged carboxylate group of alginate and calcium ion, which is called ionotropic hydrogel (Chitkara *et al.*, 2006). Owing to the high interaction, gelation occurs within seconds, which leads to poor control over geometrical shape (Chitkara *et al.*, 2006).

Hyaluronic acid contains repeating units of disaccharide and is chemically modified for 3D bioprinting, such as photocrosslinkable methacrylate hyaluronic acid with or without gelatin, thiolated carboxy-methyl hyaluronic acid with or without gelatin and gold nanoparticle to obtain soft and robust hydrogel (Kirker *et al.*, 2004; Liu *et al.*, 2007; Skardal *et al.*, 2010). These modified hydrogels have applications in regenerative medicine, such as wound healing, tumor modeling, bioprinting, cell encapsulation, etc. (Skardal and Atala, 2015).

Copyright (2014) Nature Biotechnology.

Ink from the cellulose nanofibril (CNF) hydrogel has been found biocompatible and therefore has attracted much attention in biomedical research (Liu *et al.*, 2016a,b). Native cellulose has also found application in 3D printing of food as it serves as dietary fiber and acts as bulk filling agent, rheological modifying ingredients, and reinforcing agents with good indigestibility, excellent mechanical performance, and high viscosity (Liu *et al.*, 2019). CNF gel has been mixed with other food ingredients to develop customized 3D printed healthy foods, and shows improved shape stability but decreased hardness after drying (Lille *et al.*, 2018).

Challenges

Price and speed are the most-noted limitations with 3D printing. Biobased materials have been found suitable for use in 3D printing of different structures for biomedical, food, and textile applications. For the biomedical field, 3D bioprinting shows potential for manufacturing functional organs. However, living organs are not just solid structures; they include vascular structures of different sizes to ensure fluid transfer. Ensuring this vascularization is a big challenge in 3D printing of bioorgans or tissues (Pantra and Young, 2016). In addition to vascularization, mimicking the unique and complex cellular combinations and organizations of living tissues is another challenge for 3D bioprinting. For example, a reproduction of kidney will require at least one million glomeruli and nephrons to be made (Pantra and Young, 2016), which is not only a massive undertaking but also challenge in terms of scalability.

The challenges in 3D printing of textile structures are to achieve the weave and knit structures in miniature forms as well as to ensure the flexibility and drapability, which is still not close to reality.

Summary

Since its advent in the 1980s, 3D printing technology has made notable progress in terms of direct transformation of CAD into products, making complex and intricate parts with mass customization capability, reducing overall product development time and time to market, combining several manufacturing steps into one, and manufacturing from a wide variety of materials with minimum waste and maximum material utilization. However, a number of challenges still need to be overcome such as poor dimensional accuracy and surface finish, anisotropic properties, internal defects (porosities), etc. Recent innovations in 3D printing of biobased materials opens up numerous application opportunities in aerospace, automotive, textiles, food and biomedical industries and it is believed to be the future of sustainable manufacturing (Zeidler *et al.*, 2018). The big advantage is that any product made by 3D printing of biobased materials can be completely recycled at the end of its lifecycle to create a new part, or can be disposed as biodegradable waste without causing any harm to nature.

Introduction

Concrete is a most frequently consumed materials in the construction industry and this has led to the depletion of natural resources and caused significant environment issue. According to [Celik et al. \(2014\)](#), the global cement production is approximately 3.3 million tonnes per annum and it is also expected to increase to 4 billion tonnes by the year of 2020. It was estimated that about 1 tonne of carbon dioxide (CO₂) was liberated for the production of one tonne cement ([Karim et al., 2013](#)). The industry for cement production contributes to approximately 5%–10% of the GHGs emissions in the world ([Scrivener and Kirkpatrick, 2008](#)), and 12%–15% energy used in the entire industry ([Madlool et al., 2011](#)). These greenhouse gases have severe adverse effect on the climate change. Due to increasing in suitability concern, researchers are looking for alternative materials, which could improve the sustainability in construction industry. The Supplementary cementitious materials (SCM) have been used extensively over the last few decades in the production of concrete. SCM such as granulated blast furnace slag (GBFS), fly ash (FA) and silica fume (SF) are commonly used to blend with cement to form more reactive cementitious materials. According to [Aprianti et al. \(2015\)](#), some agro-waste materials such as bagasse, rice husk ash, palm oil fuel ash (POFA) and wood waste ash, could also be incorporated in cementitious composite materials to replace normal cement.

The data provided by the United States Department of Agriculture showed that there were 64.5 million tons of palm oil being produced globally in the years of 2016 and 2017. ([Hamada et al., 2018](#)). Malaysia is the major palm oil producer and supplier worldwide. It was estimated that Malaysia will maintain the position to lead over in palm oil industry for the coming half decades and its production was projected to be 18 million tons which would be approximate 40% of the global palm oil in 2020 ([Basiron, 2015](#)). POFA is one of the significant by-product of palm oil industry. There are several chemical components present in the POFA, which mainly include SiO₂, Al₂O₃, Fe₂O₃, CaO, and MgO. It is generated from the combustion of solid waste generated from palm oil extraction including palm oil fiber, husk, kernel, empty fruit bunches and shell. These components are burnt in the power plants for producing energy. POFA is traditionally disposed through landfilling; while the yearly increasing amount of these deposits has brought burden to the authority. ([Chindaprasirt et al., 2007](#)). The widespread improper handling of the solid wastes especially the agricultural as well as industrial products has resulted in the consequence of environmental issue. [Tay and Show \(1995\)](#) highlighted that the disposal of untreated POFA can cause various diseases and hazard issue to human health. Due to the increasing demand for supplying palm oil products, the amount of respective wastes produced also escalates. Without having appropriate disposing procedures, these wastes could potentially be harmful to human as it will cause environmental issues which eventually lead to health problems and financial losses. Thus, researcher initiated to study the incorporation of POFA as materials in producing concrete. Many recent research proved that treated POFA can be used as SCM in concrete production ([Tangchirapat et al., 2009](#)). [Tangchirapat et al. \(2009\)](#) demonstrated that POFA is capable of making concrete that is having high strength of more than 60 MPa. [Fig. 1](#) shows untreated and treated POFA.

Due to the availability in large quantity while possessing proper characteristics as pozzolans, POFA has been recognized by many researchers that it is highly potential to be used as SCM in concrete production. The practice of using waste from agriculture in construction industry can be regarded as a break-through that promotes sustainability. The following sections present the physical and chemical properties of POFA, its effects on fresh properties as well as the properties in hardened state. It will be shown that POFA has high potential to be incorporated in concrete as SCM.

Properties of POFA

Physical Property

POFA can be visually inspected as greyish in colour, but the colour becomes darker when it contains more unburned carbon. [Zeyad et al. \(2016\)](#) stated that the colour of POFA is highly dependent on the process of heat treatment, which can reduce the carbon content. Lower carbon content can lead to lighter colour for POFA. It consists of irregular particles although the shape of POFA is relatively spherical ([Awal and Shehu, 2013](#)). Grinding of POFA can reduce the particle size of POFA and increase its fineness. The particle of ungrounded POFA usually has spherical shape while the grounded POFA particle exhibits angular and irregular shape. Varying size of POFA has been used and the desired size can be obtained by the grinding process. Besides, the POFA has generally specific gravity in the range of 1.86–2.6, which is much lesser when compared to cement ([Hamada et al., 2018](#)).

The pozzolanic characteristics and hydration rate of POFA are greatly influenced by its fineness. Improvement in compressive strength of concrete can be achieved when finer particle size of POFA is used ([Khalid et al., 2016](#)). The porous structure of POFA can be minimized by reducing the particle size. It is demonstrated by [Paya et al. \(1996\)](#) that the grinding process can reduce the

Fig. 1 (a) Raw POFA, (b) Treated POFA.

Table 1 Chemical compositions of POFA

Compositions	G-POFA (Johari et al., 2012)	U-POFA (Johari et al., 2012)	G-POFA (Awal and Shehu, 2013)
SiO ₂	51.18	65.01	59.62
Al ₂ O ₃	4.61	5.72	2.54
Fe ₂ O ₃	3.42	4.41	5.02
CaO	6.93	8.19	4.92
MgO	4.02	4.58	4.52
K ₂ O	5.52	6.48	7.52
SO ₃	0.36	0.33	1.28
LOI	21.6	2.53	8.25
SiO ₂ + Al ₂ O ₃ + Fe ₂ O ₃	59.21	75.14	67.18

particle size of POFA and resulted in improved porosity. The fineness and specific gravity are increased when POFA experience the grinding process to obtain finer particle size. However, Jaturapitakkul et al. (2007) discovered that although the finer particle size of POFA can improve the resistance against sulphate attack, it can decrease the concrete compressive strength.

Chemical Composition of POFA

The chemical composition of ground POFA (G-POFA) and ultrafine POFA (U-POFA) are presented in Table 1. A number of researchers reported a notable variation of POFA chemical composition. These variations could be due to the grinding process, treatment process, burning conditions, the source of materials and different practice of handling in factories (Zeyad et al., 2013; Tangchirapat and Jaturapitakkul, 2010). Compared to OPC, POFA is moderately rich in silica content. POFA has a significant amount of silicon dioxide and it can react with calcium hydroxide (Ca(OH)₂) to form calcium silicate hydrate (CSH), the strength contributing gel. Hydration of cement will release secondary product of Ca(OH)₂ which will not provide any strength to the cementitious mixture. The additional CSH gel can strengthen the bonding of mixture of concrete. Thus, theoretically, the performances of concrete in term of strength and durability will improve proportionally to the reactive silica quantity present in the POFA. The POFA having higher silica content is obtainable through combustion of palm kernel and tree (Tangchirapat and Jaturapitakkul, 2010).

Advantages of Using POFA

POFA is deemed ideal because it can be easily obtained since oil palm plantation is extensive where its supply is constant and stable. The costs associated to its pre-treatment are found to be relatively lower. Construction costs can be reduced significantly with the use of alternative waste materials while providing comparable performance. In terms of structural performance, when appropriate treatment processes are applied, POFA become highly efficient pozzolan and thus improving the concrete fresh state

property including workability as well as its hardened state properties such as strengths under tension and compression, structural porosity and resistance to the intrusion of chloride, water and gas (Johari *et al.*, 2012). In terms of environmental aspect, the use of POFA satisfies the green construction requirements as it is being recycled and reused materials. The utilization of POFA in concrete production brings about many advantages to the environment, which may include the reduction of cost for landfilling of POFA waste, reduction of carbon footprint due to cement production as well as the conservation of raw resources.

Effect of POFA on the Workability of Concrete

Workability of concrete is the ability of concrete to ease and maintain its homogeneity in fresh state under the process of mixing, placement and consolidation without any segregation. Degradation of workability was observed for concrete with high level POFA replacement due to the unburn carbon in POFA. Ahmad *et al.* (2008) reported that the slump values decreased from 190 mm to 110 mm for 15% replacement of POFA. This might be due to the size and shape of the POFA as it was not ground to make a fine particle.

Johari *et al.* (2012) removed the carbon from raw POFA through heat treatment and then grinded it into ultrafine in size. Subsequently, the treated POFA was used to replace normal cement with level of 0%–60% in making concrete. It was found that the slump value, the time for the first setting and final setting of concrete to take place became longer when the ultrafine POFA contents increased. It was explained that the ultrafine POFA provided more volume of binder paste in concrete, which lubricated the concrete and allowed smoother movement of aggregates that eventually increased the workability. Alternatively, the dosage of super plasticizer could be reduced to maintain the same slump value and hence, it will reduce total concrete production cost. With the initial setting time and the final setting time increased significantly with the increasing of ultrafine POFA, this could be again fully utilized in the hot weather concreting.

Lim *et al.* (2013) performed experimental tests to investigate the use of POFA in affecting the fresh properties of lightweight foamed concrete (LFC). From the inverted slump cone test, it was shown that the fluidity of LFC relied more on the water content of the mixes. The slump spread value increased for every increment of w/c ratio. Meanwhile, the slump values reduced slightly with the increment of POFA replacement level. It was implied in the literature that the POFA possessed characteristic of high water absorption, which decreased the fluidity of the concrete. Besides, POFA used was unprocessed and its particles were angular and porous which reduced the flowability of the LFC. The author proposed that optimum w/c ratio for 0%, 10% and 20% of POFA replacement level were 0.56, 0.54 and 0.56, respectively.

Mohammadhosseini *et al.* (2015) studied the addition of POFA in self-compacting concrete (SCC) at the replacement level of 60% and 100%. The water to binder (w/b) ratios of 0.4, 0.45 and 0.5 were used for each replacement level. The authors found that the increase in POFA content could result in the increase of superplasticizer required to achieve workability. Meanwhile, Nagaratnam *et al.* (2016) studied the workability of binary and ternary blends by using cement, fly ash and POFA in SCC at the replacement level of 10%–40%. All the mixes satisfied the requirement of SCC in terms of passing ability, filling ability and segregation resistance. The authors noticed that the implementation of POFA in SCC at high level replacement required more superplasticizer to obtain self-compacting ability which agreed with the findings of Mohammadhosseini *et al.* (2015). It was explained that POFA possessed high water absorption and its nature of hygroscopic reduced the water available for hydration to take place in the concrete. The author concluded that ternary blend of cement, fly ash and POFA had the optimum workability when compared to binary mix.

Zeyad *et al.* (2018) studied the impact of carbon-laden POFA (GPOFA) and ultrafine carbon-free POFA (UPOFA) on workability at the replacement level of 0, 20, 40 and 60%. The authors observed that the increase in UPOFA content can improve the slump flow value when compared to control mix. Meanwhile, GPOFA had negative effect on the workability of concrete. The authors explained that UPOFA can enhance workability by increasing the paste volume of the cementitious mixture.

Effect of POFA on the Hardened Properties of Concrete

Compressive Strength

The compressive strength of concrete is regarded as one of the utmost important mechanical behaviors whereby it can significantly affect the outcomes of any structural designs. Thus, aiming to bring forward the POFA concrete to the current construction industry, it is necessary to discern the effect of POFA on the concrete compressive strength. In general, the POFA is having the characteristics of improving the compressive strength of concrete (Tangchirapat *et al.*, 2012; Ranjbar *et al.*, 2016; Sata *et al.*, 2007). Yet, the present researches have shown that the strength improvement by the POFA is limited to certain proportion of its substitution. However, the concrete compressive strength may reduce should the POFA replacement level is outside of the range (Ahmad *et al.*, 2008; Sata *et al.*, 2004; Muthusamy *et al.*, 2015). The dosage ranges of the POFA in providing the improvement of compressive strength varies with the sources and properties of the POFA. These properties could include chemical composition, particle size, pozzolanic reactivity, etc. (Hussin *et al.*, 2010; Jaturapitakkul *et al.*, 2011). Hence, the optimum dosage for POFA in concrete will also change if a different type of POFA is used, and several literatures showed that it will generally be at lower replacement level of 10%–30% by cement weight (Islam *et al.*, 2016; Ismail *et al.*, 2011).

Tangchirapat *et al.* (2012) used grounded palm oil fuel ash (G-POFA) which possessed higher fineness with intention to strengthen the concrete mechanical properties made up of recycled concrete aggregates. The quantity of G-POFA incorporated was in the range of 0%–50% by weight of the total binder content. It was observed that the concrete compressive strength increased

when 20% of G-POFA was used to replace cement. [Ahmad et al. \(2008\)](#) found that concrete mixture having 15% of POFA can give the concrete an optimum compressive strength. However, the concrete compressive strengths of 5% and 10% of POFA were less than the anticipated strength. Moreover, POFA was also used to replace cement in producing lightweight concrete ([Islam et al., 2016](#)). In the study, the incorporation of POFA in the concrete up to 25% obtained comparable compressive strength as the normal concrete. The replacement level of 10%–15% of POFA improved the compressive strength of concrete. In the investigation, the compressive strengths of POFA obtained were more consistent than the conventional OPC concrete. This is because the POFA was less sensitive to poor curing since the POFA was finer than OPC, which provided filler effect to the concrete.

Furthermore, [Awal and Hussin \(2011\)](#) discovered that the compressive strength of POFA based concrete at the ages of 1 day, 7 days and 28 days are lower than control concrete. They also observed that during the early age, the strength gaining rate of the POFA concrete was relatively slow when compared to cement based concrete but in later ages it was faster. From this study, it can be deduced that the rate of strength gaining in pozzolanic concrete is slower compared to the cement based concrete. Besides, [Ranjbar et al. \(2016\)](#) examined the effect of ground POFA on the compressive strength of self-compacting concrete (SCC). The study included three replacement levels which were 10%, 15% and 20% of cement by weight. For the early compressive strength (7 days), POFA concrete achieved lower strength than the normal concrete for every level of cement replacement. Nevertheless, the POFA concretes achieved comparable long-term compressive strength, especially the strength after 180 days. The author implied the observation as the effect of pozzolanic activity of ground POFA whereby longer duration is required to build up calcium silicate hydrate (C-S-H) gel. High contents of SiO_2 in POFA react with calcium hydroxide ($\text{Ca}(\text{OH})_2$) from the cement hydration to generate C-S-H gel. $\text{Ca}(\text{OH})_2$ is a secondary product from cement hydration which will not provide any bonding strength to the concrete. The C-S-H gel is the key agent that binds the aggregates together and gives strength to concrete. On top of that, [Sata et al. \(2007\)](#) also investigated the compressive strength behavior of G-POFA on high strength concrete (HSC) up to the age of 180 days. They found that (1) the HSC containing 10% G-POFA achieved higher compressive strength than the concrete made up of 0%, 20% and 30% POFA at the 7 days. (2) For the later strengths, the 20% G-POFA concrete yielded higher strength than those of 0% G-POFA, 10% G-POFA and 30% G-POFA concretes.

[Hussin et al. \(2010\)](#) made a study related to the effects of various factors on the compressive strength of aerated concrete incorporated with and without POFA. These factors included the sand size and its distribution, the quantity of gas foaming agent, as well as the dosage of superplasticizer. The investigation showed that the aerated concrete containing POFA acquired higher strength than the concrete made up of ordinary Portland cement. [Jaturapitakkul et al. \(2011\)](#) used three different sizes of ground POFA in mortar to investigate the compressive strength. The mean particle size of small particle (SPA), medium particle (MPA) and large particle (LPA) are 12.3 μm , 13 μm and 30.8 μm respectively. They found that (1) the compressive strength of control mortar is higher than POFA base mortar up to the age of 7 days, (2) mortars mixed with SPA yielded higher compressive strength than the control mortar from 28 days and onwards, and (3) mortars mixed with MPA and LPA yielded lower compressive strength than the control mortar strength at all ages. This had shown that the finer POFA exhibited better pozzolanic property, of which the voids in the mortar can be filled, and hence giving a higher compressive strength.

Tensile Strength

The structural members, particularly the beam and column, require ample tensile strength to resist tensile stress such as the bending stress in beam and buckling of unrestrained column. It is known that the concrete is weak in tension, and yet, it is still widely used provided that the concrete is adequately reinforced with steel reinforcement and its cracking strength is higher the minimum requirement. Therefore, when considering the mechanical property of POFA concrete, the influence of POFA on the concrete tensile strength should not be neglected. Several literatures had reported the positive influence of POFA on the tensile strength ([Lim et al., 2013](#); [Aldahdooh et al., 2014](#)). Nevertheless, its negative effect on the tensile strength was also discovered by the researchers ([Altair et al., 2012](#); [Islam et al., 2016](#); [Ranjbar et al., 2016](#)). In this connection, studies were made to improve the performance by modifying the POFA as well as incorporating additive ([Alsubari et al., 2018](#); [Mohammadhosseini et al., 2018](#)). The tensile strength of concrete can generally be determined experimentally through conducting flexural strength test or splitting tensile test.

In the study of [Lim et al. \(2013\)](#), light foam concretes (LFC) were incorporated with POFA and their tensile strengths were determined. The concretes containing 10%–20% possessed greater splitting tensile strength than the control concrete at all curing ages. As additional C-S-H was formed by the incorporation of POFA, bonding property of the LFCs was enhanced and higher imposed load was required to split the cylindrical specimens. Besides, it was also noted that the trend of tensile strength development was similar to the compressive strength and their relationship was found to be linear. Furthermore, [Aldahdooh et al. \(2014\)](#) studied the influence of POFA on the flexural and tensile strengths of fiber reinforced cementitious composites. The aim of the study was to obtain cementitious composites, which are ultra-high performance and at the same time are environmentally green. In the investigation, the authors found that the U-POFA could improve the flexural and uniaxial tensile capacity of the cementitious composite.

Nevertheless, some literatures had shown that the incorporation of POFA can reduce the tensile strength of concrete. [Ranjbar et al. \(2016\)](#) partially replaced the ordinary Portland cement with POFA in producing self-compacting concrete (SCC). The replacement level was in the range of 10%–20% and from the tests, the early-age and long term flexural strengths of POFA concrete in this range of replacement level were slightly reduced. The authors explained that, with the support of permeability test, the decrement might be due to porous structure of SCC having POFA, which caused stress concentration that weakened the bonding of aggregate and paste. Moreover, [Islam et al. \(2016\)](#) investigated the effect of curing conditions on the tensile strength of POFA

concrete through tensile splitting test and flexural test. The curing conditions included air curing (AC), full water curing (WC) and partial water curing (PWC). In the tests, the POFA replacement levels varied from 0% to 25%. Based on the tensile splitting test, the strengths of POFA concrete were all less than the conventional concrete, except for the case of concrete having 5% POFA under PWC condition. The splitting tensile strength increased by approximately 10% when POFA content increased from 0% to 5%, but the strength dropped for further POFA content increment. The concrete specimens cured under WC condition acquired higher strength than that cured under AC and PWC conditions. In the study, similar increment of tensile strength as the compressive strength was not observed. This had shown that POFA was not effective in providing improvement to the bond between aggregate and cement matrix.

Altwaier *et al.* (2012) assessed the flexural strength green-engineered cementitious composite (ECC) incorporated with POFA at the ages of 3, 28 and 90 days by conducting four-point bending tests. They demonstrated that by increasing w/b ratio, strengths at first cracking point as well as flexural strengths of all ECCs were reduced. This was primarily due to the increase in the pore volume in the matrix. Besides, the dilution effect occurs when the POFA content became higher and this had contributed to the declining of initial cracking strength. As the POFA to cement ratio increased, the cracking strength at the initial point of the ECC decreased. At low w/b ratio, the flexural strengths of POFA–ECC mixtures were higher than that of the control mixture. Meanwhile, when w/b ratio is higher, the flexural strengths of all mixtures containing POFA were higher than that of the control mixture. The increase in fiber–matrix interfacial bond concurrently reduced the flexural deflection capacity.

As a consequence of possible reduction in the mechanical property of POFA concrete, Alsubari *et al.* (2018) used modified treated POFA (MT-POFA) in making self-compacting concrete (SCC). The volumes of POFA used were 0%, 30%, 50% and 70%. Based on the experimental study, the concrete splitting tensile strength improved when POFA content increased from 0% to 30%, but it reduced for the further increment of POFA content up to 70%. The highest tensile strength obtained from the test was for the concrete containing 30% of POFA. In addition, the investigation regarding the incorporation of waste carpet fibers into POFA concrete was performed by Mohammadhosseini *et al.* (2018) as an impact from the increasing waste produced by textile and carpet industries. The waste carpets were then modified and incorporated into the concrete production with the purpose of improving its mechanical property, particularly the tensile strength. The POFA content was kept constant which was 20% of the cement content while the fiber contents included were 0%, 0.25%, 0.5%, 0.75%, 1% and 1.25%. The POFA concretes were found to have higher tensile strengths than the control concrete where the improvement was in the range of 15%–26%. The results also indicated that the incorporation of POFA into concrete could enhance the splitting tensile strength. However, the increment was more obvious for long-term strength and this was due to slow pozzolanic reaction provided by POFA. It was concluded in the study that the addition of both POFA and waste carpet fibers was capable of improving the interfacial transition zone, the region between the aggregate and cementitious paste of the concrete, thus increasing the tensile strength.

Modulus of Elasticity

Elastic modulus of concrete is also a significant mechanical property that is used to determine the concrete hardness and its abrasion resistance. In general, the concrete elastic modulus is closely related to its compressive strength. The elastic modulus of concrete will increase when its compressive strength increases. Yet, most of the literatures show negative effect of POFA on the concrete elastic modulus although the compressive strength has been improved (Awal and Hussin, 2011; Sata *et al.*, 2004; Islam *et al.*, 2016). On the other hand, there are some researches proved that POFA possesses positive effect on improving the elastic modulus of concrete (Tangchirapat and Jaturapitakkul, 2010; Hussin *et al.*, 2010; Alsubari *et al.*, 2018). In fact, the aggregate will be mainly contributing to the concrete elastic modulus while the incorporation of POFA may change the bonding behavior of the aggregate and the cementitious paste.

Research carried out by Sata *et al.* (2004) indicated that the G-POFA content up to 30% had contributed insignificant effect on concrete modulus of elasticity. It was also proposed that the decrease in the coarse aggregate of concrete as a result of the incorporation of G-POFA had caused slight reduction in the elastic modulus. Besides, the static elasticity of concrete containing 30% POFA and concrete without POFA were measured by Awal and Hussin (2011). The results showed that the POFA concrete has lower modulus of elasticity than the normal concrete. The pozzolanic exhibit of 30% POFA exhibited lower strength than the hydration of OPC. Furthermore, the elastic moduli of concrete made up of varying POFA contents and cured under air (AC) and full water (WC) conditions were determined by Islam *et al.* (2016). From the investigation, concrete elastic modulus decreased gradually with the increment of POFA content (0% to 25% POFA). This was explained in the literature that the POFA had limited effect on improving the interfacial zone of concrete. Nevertheless, the reduction in the elastic modulus was minimal, for instance, the elastic modulus decreased by 15% when POFA contents increased from 0% to 25%. Meanwhile, the elastic modulus of water-cured concrete was approximately 10%–23% higher than the corresponding air-cured concrete.

Hussin *et al.* (2010) carried out study on plain aerated concrete specimens and found that the POFA aerated concrete possessed higher stiffness value and thus having greater elastic modulus than the control concrete. The partial replacement of cement by POFA enabled pozzolanic reaction to take place, which produced additional C-S-H gel, and hence resulted in densification of lightweight concrete internal structure, making it stiffer. Besides, Tangchirapat and Jaturapitakkul (2010) deduced that use of coarse POFA (CP) and fine POFA (FP) has insignificant effect on altering the concrete elastic modulus as compared to OPC concrete. In fact, the strength provided by the coarse aggregates has more effect in determining the concrete elastic modulus rather than the strength from cementitious paste.

Moreover, [Alsubari et al. \(2018\)](#) incorporated modified treated POFA (MT-POFA) in making SCC. It was shown that the elastic moduli increased slightly when MT-POFA content increased from 0% to 30% for the concretes at age of 28 days and 56 days. This was due to the pozzolanic property of MT-POFA which improved the bonding between cement paste and aggregate. Yet, the elastic moduli decreased significantly for the subsequent increment of 50% and 70% POFA. The concrete elastic modulus is primarily affected by the coarse aggregate content. Therefore, the reduction of elastic moduli for concretes of 50% and 70% was due to the decrease in aggregate-to-paste ratio, where the aggregate content reduced. In addition, [Lau et al. \(2018\)](#) incorporated POFA and lime-treated sewage sludge in making lightweight aggregate and was termed as Posslite LWA. In the study, the Posslite LWA was used to produce concrete. It was found that the concrete elastic modulus made with Posslite LWA was slightly lower than the control concrete, but, it was still comparable to the control concrete. Similarly, the reduction of elastic modulus was attributed to the weaker interfacial transition zone of concrete containing Posslite LWA.

Resistance to Chlorine Penetration

Throughout the service lifespan of any concrete structure, there is possibility for the chloride to penetrate and travel through the pores in concrete, whereby the corrosion of the steel reinforcement may be initiated. This is particularly true for the application of concrete in the marine environment where the source of chlorine will be abundant. Therefore, the ability of a concrete to resist and prevent the penetration of chloride ion is essential to be investigated. The chlorine penetration resistance can generally be evaluated by conducting the rapid chloride penetration test (RCPT) or rapid migration test (RMT). Several works made by past researchers showed that the POFA can reduce the chloride penetration of concrete ([Ofuyatan and Edeki, 2018](#); [Ranjbar et al., 2016](#)). Besides, current researches focused on the modification of POFA by incorporating some industrial wastes to improve the durability of concrete ([Chindaprasirt et al., 2008](#); [Alsubari et al., 2018](#); [Lau et al., 2018](#)).

[Ofuyatan and Edeki \(2018\)](#) conducted RCPT for self-compacting concrete incorporated with 0%–30% of POFA. It was found that the surface resistivity to chloride diffusion of the concrete increased when the POFA content increased. Also, it was shown that the rate of surface resistivity increment reduced gradually when the POFA replacement level is high. The POFA added is able to refine the concrete pore structure by densifying the structure and thus reduce the void content. Furthermore, [Ranjbar et al. \(2016\)](#) determined the effect of 0% to 20% of POFA in concrete on the hydrochloric acid resistance. The concrete samples were immersed in the solution containing 3% of HCl acid for 75 days, and afterwards, the mass loss and compressive strength of the samples were determined. The mass loss of the concrete specimens reduced when the POFA content increased, indicating improvement of resistance to the acid. Similarly, the loss of compressive strength after the acid attack reduced with the increment of POFA content from 0%–20%. The improvement in the resistance was mainly due to the pozzolanic property of POFA in providing additional CSH gel by converting the weaker product of $\text{Ca}(\text{OH})_2$. Also, the author explained that better finishing surface of POFA concrete had provided fewer voids on the surface of concrete, resulting in minimum entrance to acid.

[Chindaprasirt et al. \(2008\)](#) presented a study regarding the uses of POFA, rice husk ash (RHA) and fly ash (FA) in improving chlorine penetration resistance of concrete. At 20% and 40% replacement levels, POFA was shown to effectively reduce the passing charge from 1900 C to 1050 C respectively. Coulomb charges for blended pozzolans of POFA and FA were very low which were 1250°C and 850°C for mortars made up of 20% and 40% of the blended cementitious materials respectively. These values were much lesser than the mortars made with single pozzolan at the equal replacement levels. Meanwhile, incorporations of 20% and 40% POFA showed the reductions of depths for the conducted rapid migration test (RMT). Accelerated chloride penetration depths of 20% and 40% of POFA-FA blended pozzolans were also improved to 5.5 mm and 4.0 mm respectively. The results above had also been verified by actual chloride penetration test in which the mortar was immersed in the solution containing 3% of sodium chloride for 30 days. The outcomes were similar to the test results obtained from RMT. As for the RCPT, although minor magnitude differences were observed but similar trends were demonstrated. All these indicated that POFA as well as FA and RHA (all are pozzolans) increased nucleation sites for hydration products precipitation, reducing $\text{Ca}(\text{OH})_2$ and ameliorated the mortar permeability. This had contributed to the significant improvement in chloride penetration resistance.

Besides, the modified treated POFA (MT-POFA) was incorporated in the concrete in the study performed by [Alsubari et al. \(2018\)](#). The concretes were made by 0%, 30%, 50% and 70% of POFA content. The results indicated that the chloride penetration resistance reduced significantly where the improvement of 40% in resistance was observed, when 30% POFA was incorporated. The resistance decreased for 50% and 70% POFA content concretes, but they are still higher than the control concrete. The improvement of chloride penetration resistance in POFA concrete was mainly due to the CSH components acquired from pozzolanic reaction of POFA which reduced the concrete porosity and permeability. On top of that, the Posslite lightweight aggregate (LWA) made up of POFA and lime-treated sewage sludge was used by [Lau et al. \(2018\)](#) in producing lightweight concrete. The chloride penetration test conducted in the study showed that the Posslite LWA concrete possessed similar resistance to chloride penetration as the control concrete for the short-term and long-term cases. The author implied that the Posslite LWA possessed dense and hard shell, which prevented the intrusion of chloride ion into the concrete. In addition, [Mohammadhosseini et al. \(2017\)](#) used POFA and waste carpet fibers in producing green concrete. The RCPT was performed for the concrete containing POFA volumes of 0% and 20% while the waste carpet fibers content varied from 0.25% to 1.25%. The results showed that POFA increased the chloride penetration resistance of concrete at any content of waste carpet fibers added. Also, the increment of waste carpet fiber content showed positive effect on the resistance but the increment reached maximum at 1% of waste carpet fiber. By conducting the scanning electron micrograph (SEM) analysis, the author explained that the POFA had converted $\text{Ca}(\text{OH})_2$ into CSH gel which breakdown the bigger pores of concrete, densifying the concrete structure in a microscopic level.

Drying Shrinkage

The drying shrinkage occurs in the concrete when the process of drying out takes place after the concrete is hardened. The concrete drying shrinkage is primarily because of the loss of water component in the concrete through the micro-pores. This can result in the occurrence and subsequently growth of microcracks at the surface of the concrete. Harmful substances can travel into the concrete easily which eventually can undesirably affect the concrete durability. Therefore, it is particularly essential to assess the drying shrinkage of POFA concrete.

Tangchirapat and Jaturapitakkul (2010) studied shrinkage of concrete incorporating ground coarse POFA (CP) and ground fine POFA (FP). The higher water-to-binder (w/b) ratio of CP incorporated concrete than the OPC concrete has caused it for not having a reduced drying shrinkage. The CP concrete exhibited almost the same shrinkage as that of OPC concrete in the long term. Concretes with 10%–30% of FP replacement however exhibited 10%–17% lesser drying shrinkage than the normal concrete. Since the FP exhibited better pozzolanic property, its incorporation in concrete could reduce the pore size by filling the large pores. The refinement of the pore is vital in reducing water loss, and thus the drying shrinkage. Besides, no shrinkage was observed by Hussin *et al.* (2010) for water cured aerated concrete specimen as it was continuously immersed in water for 1 year. However, swelling took place for the concrete because it was fully saturated. Meanwhile, shrinkage was however detected for the air-cured samples, indicating the specimens that are in contact with drier atmosphere are more subjected to drying shrinkage. It was proven that the POFA is able to minimize the drying shrinkage in concrete. Furthermore, Ranjbar *et al.* (2016) investigated the effect of POFA content of 0%–20% on the shrinkage of SCC. The results showed that the drying shrinkage strain of POFA concrete reduced at any replacement level up to 20%. When compared to the reference concrete, the maximum reduction of shrinkage was observed in the 10% POFA concrete. Meanwhile, the lowest reduction of shrinkage was found in 20% POFA concrete. The author explained that although the POFA content had increased the volume of pore in concrete, however, the pozzolanic property exhibited by the POFA transformed the larger pores into smaller one, providing a higher packing effect on the microstructure of the concrete.

Nevertheless, some researches indicated that the POFA content can have negative effect on shrinkage of concrete. Shrinkage values of POFA concrete were measured by Awal and Hussin (2011) and they found that the POFA concrete exhibited greater shrinkage strain than that of 100% OPC concrete. At 28 days, OPC concrete showed a shrinkage magnitude of 275.2×10^{-6} . Meanwhile, with 30% POFA replacement, shrinkage of 328.8×10^{-6} was achieved and it was 18% more than that of OPC concrete. This may be due to the different nature of the paste, which absorbed more water and thus led to the development of strain by shrinkage. On top of that, Mohammadhosseini *et al.* (2017) incorporated POFA an polypropylene (PP) carpet fibers in producing green concrete. The POFA concretes of 0% and 20% replacement level were casted while the PP carpet fibers content varied from 0% to 1.25%. The drying shrinkages of concretes reduced with the incorporation of PP carpet fiber in any volume used. In the test, concrete containing 0.75% carpet fibers acquired the minimum shrinkage strain. The carpet fibers were capable of improving the concrete tensile strength and thus reduced the possibility to crack. Also, when comparing POFA concrete and the OPC concrete, the shrinkage experienced by the POFA concrete was lower than the OPC concrete. Besides, the POFA and the waste metalized plastic (WMP) fibers were used by Mohammadhosseini and Tahir (2018) to make concrete. The POFA of 20% replacement level as well as 0%–1.25% of WMP fibers were incorporated in the concrete and their effects on drying shrinkage were studied. In the concrete without POFA, the highest shrinkage strain was observed in 0% WMP fibers while for the remaining replacement level of fibers, the shrinkage strain reduced. The maximum reduction in shrinkage was found in concrete incorporated with 0.75% of WMP fibers. The bridging effect provided by the fiber along the cracks reduced the shrinkage strain of the concrete. However, it was found that POFA concrete experienced higher shrinkage than the reference concrete for all volumes of WMP fibers. This could most probably be due to the lower rate of pozzolanic reaction attributed by the POFA. In short, POFA might not be helpful in reducing the concrete shrinkage at early age.

Water Permeability

The water permeability of a concrete is also a critical aspect in examining the durability of the concrete. The concrete water permeability can be examined by the water absorption of concrete. It refers to the ability of the concrete in preventing the water penetration into the concrete through the pores presented. Hence, water permeability is strictly related to the concrete porosity. The neglect of water permeability in concrete can result in various failure mechanisms of concrete due especially harmful agents are presented adjacently. Thus, the influence of POFA addition on the concrete water permeability is noteworthy to be studied.

Tangchirapat and Jaturapitakkul (2010) revealed that by utilizing of 10%–30% of ground coarse POFA (CP) and ground fine POFA (FP) as a cement replacement in concrete, promising results in water permeability were obtained. It was proven that FP concretes were having lower water permeability values than those of CP concrete as well as the reference concrete. Besides, water permeability of ground POFA concrete declined when its strength under compression increased. This had shown that water permeability of concrete is closely related to the compressive strength. It was implied that ground POFA possessed high pozzolanic properties that could densify the concrete morphology. Thus, higher volume of paste and less aggregate could be used and this combination provided concrete with lower water permeability. Furthermore, Ofuyatan and Edeki (2018) conducted water absorption rate test to study the concrete permeability by water that contained 0%–30% of POFA. The tests were carried out for the concrete at the age of 14, 28, 56 and 90 days. The experimental results indicated that the water permeability of concrete at all ages reduced when the POFA content increased. The maximum water permeability reduction was 24% and it was observed in the concrete incorporated with 30% POFA. The POFA can act as filler to seal the pores of the concrete, thereby reducing the permeability of water.

The surface absorption test was performed by [Ranjbar et al. \(2016\)](#) on the self-compacting concrete containing 0%–20% POFA after 28 and 56 days of curing. The results proved that the water permeability decreased when the POFA volume increased. The minimum water permeability was found at 20% of POFA content. Even though the concrete containing 20% POFA possessed lower compressive strength than any other replacement level, it had the lowest water permeability among the concretes. The reduction of water permeability was most probably due to the densely packed microstructure of POFA contained matrix, which had finer pores. Additionally, the water permeability of MT-POFA incorporated self-compacting concrete was also investigated by [Alsubari et al. \(2018\)](#). The levels for cement to be replaced MT-POFA were 0%, 30%, 50% and 70%. It was observed in the water absorption test that water permeability of 30% and 50% MT-POFA concrete decreased significantly by approximately 35% and 27% at 56 days of curing. The water permeability of 70% MT-POFA was higher than the concrete made by control mix. The author implied that the increase in water permeability was because of the slow pozzolanic reaction exhibited by the MT-POFA which resulted in incomplete filling of voids in the concrete. However, although the water permeability 70% MT-POFA concrete was greater than other concretes, it was still rated as good concrete according to the CEB-FIP requirement. Moreover, [Mohammadhosseini and Tahir \(2018\)](#) used POFA and waste metalized plastic (WMP) fibers in producing concretes and studied their water permeability. The results showed that the concrete water permeability reduced when the fiber volume increased from 0% to 0.5%, but it increased for further increment of fiber content up to 1.25%. It was explained in the literature that the fibers in high amount could cause balling effect where it affected and disturbed the compaction of concrete which eventually led to the forming of cavitation in the concrete. Nevertheless, the POFA had improved the durability of concrete whereby the water permeability reduced for all fiber volumes added. This was attributed to the finer and smaller pores due to the hydration product from pozzolanic reaction of POFA.

Sulphate Resistance

When concrete is externally exposed to sulphate, the transportation of sulphate ions into concrete core through the micro-pores can result in severe deterioration of concrete properties. The cementitious matrix of the concrete will be attacked by the sulphate as a result of complex reaction between inter-action of aggressive solution and the cement paste compound took place ([Ofuyatan and Edeki, 2018](#)). An expansive compound, which usually referred to as gypsum will form which cause the concrete to crack, lose strength and soften. Hence, the potential of POFA content in providing improvement to concrete sulphate resistance should be investigated thoroughly.

The effect of 0%–30% of POFA contents on the concrete sulphate resistance was investigated by [Ofuyatan and Edeki \(2018\)](#). The sulphate resistance was measured based on the mass loss of concrete as well as the loss in concrete compressive strength. From test of weight loss, it was observed that the concrete weight loss reduced when the POFA content increased from 5% to 30%, indicating improvement of the concrete to sulphate attack. For the loss of compressive strength, the loss decreased for the POFA content of 5%–20%; while for the POFA volume up to 30%, the loss of compressive strength increased. This could potentially be due to the incomplete pozzolanic reaction of the POFA, especially for the inner portion of the concrete. The outer part of the concrete exhibited a more completed pozzolanic reaction and thus preventing intrusion of sulphate ion. Besides, [Jaturapitakkul et al. \(2007\)](#) performed study to examine the effects of POFA on improving concrete sulphate resistance. By exposing concretes to solution containing 5% of MgSO_4 solution for 2 years, the concrete expansion and loss of concrete compressive strength were determined. The authors stated that the grounded POFA possessed high pozzolanic properties, but it was not for the ungrounded POFA. In this investigation, it was proven that the POFA fineness played an important role improving concrete resistance to sulphate attack. The experimental works showed that the concrete made with finer POFA experienced lesser the expansion and also compressive strength loss reduced.

[Tangchirapat et al. \(2009\)](#) investigated the use of highly fine ground POFA (GPA) in replacing cement to make high strength concrete (HSC). The authors found that the HSC having incorporated with GPA possessed better sulphate attack resistance. Furthermore, [Ranjbar et al. \(2016\)](#) studied the effect of 0%, 10%, 15% and 20% of POFA content in self-compacting concrete on its sulphate resistance. The tests were carried out by immersing the concrete samples in 5% magnesium sulphate solution and the concrete compressive strengths were measured afterwards. The losses of compressive strengths for 0%, 10%, 15% and 20% POFA concrete were approximately 9.5%, 8.2%, 7.8% and 7.3% respectively. It was clearly observed that the concrete resistance to sulphate attack enhanced when the sulphate content increased. Similarly, the pozzolanic reaction of POFA converted free $\text{Ca}(\text{OH})_2$ into CSH gel which provided the concrete with a more densely packed pore structure. On top of that, [Mohammadhosseini et al. \(2018\)](#) used both POFA and waste carpet fibers in producing green concrete. The POFA content used was 20% while the waste carpet fibers content varied from 0.25% to 1.25%. The concrete sulphate resistance was determined by calculating the strength loss of the concrete specimen after immersing in magnesium sulphate solution for 365 days. All concretes containing POFA exhibited lower strength loss than the OPC concretes, indicating improvement in concrete sulphate resistance. Meanwhile, the concrete containing 0.25% of waste carpet fibers showing the lowest reduction in compressive strength. The bridging effect provided by the waste carpet fibers prevented the formation of crack of concrete.

Future Applications and Research

Recently, palm oil fuel ash (POFA) has become a significant research interest, especially in Malaysia due to its abundance as a result of solid wastes generated from agricultural industry. Based on the present literatures, researches concerning the incorporation of POFA as supplementary cementitious material in concrete, particularly its effects on the concrete workability,

mechanical properties and durability, has been carried out and reported extensively. Hence, the following statements are some recommendations for future applications and research with regard to POFA in concrete industry.

- Past researches have shown the incorporation of POFA is notable in enhancing the durability of concrete by providing a more densely packed microstructure. Therefore, POFA is potential to be used to produce high performance concrete (HPC) and the research regarding this is yet still limited.
- It is reported in the literatures that POFA contains as much as 60% silica and significant portion other hard particles. Therefore, due to the existence of rich siliceous material, POFA could be a potential material for possible inclusion in metal matrix composite (MMC) composites for improved properties. Few researches are made on the utilization of POFA in MMC.
- Researches of POFA are found in producing self-compacting concrete (SCC) and lightweight concrete (LWC) due to its ability in improving concrete workability. However, there is no approach found to bring forward their application to construction industry. It will be beneficial if standardized approaches are developed to use SCC and LWC as this can greatly reduce the construction time, materials and energy.

Conclusions

The literature review summarizes the current researches that have been carried out on using POFA in concrete industry. POFA is a green agriculture waste material, which can be obtained with relatively low cost. The review encapsulates the various usage of POFA as construction materials, highlights of some important findings and results with regard to concrete hardened state properties, analysis of POFA in current applications and some recommendations for further research. Based on the review, conclusions are drawn and listed below:

- POFA can be easily obtained from the oil palm plantations in Malaysia, Indonesia and Thailand. It can be constantly and extensively supplied by the plantations.
- The pre-treatment costs are found to be relatively lower. When appropriate treatment processes are applied, POFA become highly pozzolanic and the concrete fresh state property and the concrete hardened state properties will be improved.
- The slump value, the initial setting time and ultimate setting time generally increase when fine POFA contents increase. Addition of POFA is capable of improving the concrete workability and thus it has high potential to be incorporated in self-compacting concrete (SCC).
- The improvement on concrete compressive strength containing POFA relies on the POFA fineness as well as its pozzolanic reactivity. Most literatures show that the optimum POFA content for strength is limited to low content with maximum volume substitution of approximately 30% due to slow strength gaining rate provided by POFA pozzolanic reaction.
- The durability of the concrete improve with the addition of POFA. The incorporation of POFA in concrete fills the voids of concrete, provides a more densely packed microstructure and thus minimizes the concrete porosity.

Introduction

Oil and natural gas industries consume a large quantity of water for preparing water-based drilling fluids. Water-based drilling fluids are pumped through the downhole tubing during the drilling process and are circulated back to the surface through the casing annulus and collected in the return pit. At the end of recycling of the drilling fluids, large quantities of drill cuttings or solid materials are generated from the drilling fluid waste. In the drilling process of oil and gas wells generally, two types of wastes are generated: liquid drilling fluids waste and drill cuttings (Onwukwe and Nwakaudu, 2012). The oilfield drilling fluids waste produces the second largest volume of total waste (Haut *et al.*, 2007). The disposal of the drilling fluid wastes has proven to be one of the most difficult environmental problems in the world as the above wastes are made of various minerals, clays, organic materials, and other solids (Zou *et al.*, 2011). The most common toxic substances present in drilling fluid wastes contain a high concentration of chromium (a heavy metals), inorganic salts, biocides, hydrocarbon and solid cuttings. These toxic substances resulting from the chemical additives used for the preparation of the drilling fluids (Ayotamuno *et al.*, 2007). These oilfield waste materials have the ability to cause cancer and its toxicity affects mankind and the eco-system (Ismail *et al.*, 2017). The physical and chemical properties of the drilling fluid wastes are given below Table 1. Typical elemental composition of common constituents of drilling fluid waste is given in Table 2.

Discharge of drilling fluid waste containing drill cuttings into seabed is the most significant effect on the environment during offshore drilling operations. A case study had shown the impact of toxicity to the marine population due to presence of additives in the drilling fluid waste (Gbadebo *et al.*, 2010). The study conducted by Soegianto *et al.* (2008) was also showed that the effect of toxicity due to drilling fluid waste. Oil-based drilling fluid wastes are the most toxic drilling fluid compared to water or synthetic based drilling fluids (Ismail *et al.*, 2017). The removal of such toxic contaminants from the drilling waste and drilling wastewater is most desirable before their final disposal. The common methods to dispose the drilling fluid waste and drilling wastewater are: gravity separation, baffle and vacuum separation. In deep drilling well, when the components of drilling fluid waste are more complex, the density of drilling fluid waste becomes higher. To minimize the environmental impact of drilling fluid waste is one of the most important challenges in the petroleum industry (Shon *et al.*, 2016).

The solid-liquid separation by the coagulation and flocculation plays an important role in waste management technique. The effective waste management techniques are waste minimization, recycling, solids control, treatment, and disposal (Onwukwe and Nwakaodu, 2012). The term flocculation and coagulation are often used interchangeably although the two processes are quite different. Coagulation is the process by which components of a stable suspension in solution are destabilized by the addition of an inorganic chemical. On the other hand, the process of forming larger agglomerates of particles in suspension or of small agglomerates already formed as a result of coagulation by high molecular weight polymeric material is called flocculation (Bratby, 1980; Karmakar, 1994).

Generally, flocculating agents in the waste water treatment can be classified broadly into two categories: inorganic and organic. The inorganic flocculants are mostly the salts of multivalent metals like aluminium and iron. Aluminium compounds (alum) with a chemical formula $\text{Al}_2(\text{SO}_4)_3 \cdot 14\text{H}_2\text{O}$ are most often used in waste water treatments. The organic flocculating materials are further classified into natural and synthetic polymeric materials (Zou *et al.*, 2011). The synthetic polymers are based on various monomers but natural polymers are mostly polysaccharides (Kolya *et al.*, 2017). Natural polymers, as well as synthetic anionic, cationic and non-ionic polymers are widely used in flocculation studies. Natural polysaccharides have been used extensively as flocculants but their performances are not good. Natural polymers are mainly polysaccharides which are easily available from reproducible farm or forest resources. They are inexpensive and fairly shear stable and biodegradable but less efficient as flocculants. On the other hand, the polyacrylamide-based synthetic polymers are efficient flocculating agents, but they are shear degradable. Hence both the synthetic and natural organic flocculants have their own advantages and disadvantages (Singh *et al.*, 2003, 2009, 2014; Kolya *et al.*, 2017). A new class of polymeric flocculants i.e., the graft copolymers have been developed which are synthesized using natural and synthetic polymers. Graft copolymerization is a useful technique for modifying the chemical and physical properties of natural and synthetic polymers. Grafting of the synthetic polymer is a convenient method to add new properties to a natural polymer with minimum loss of the initial properties of the substrate. Many researchers have carried out grafting reactions of acrylamide onto the natural polysaccharides like starch, amylose, amylopectin, guar gum/hydroxypropyl guar gum, xanthan gum, sodium alginate and carboxymethyl cellulose (CMC) (Rath and Singh, 1997; Karmakar and Singh, 1998; Tripathy *et al.*, 1999, 2000, 2001; Nayak and Singh, 2001; Pal *et al.*, 2005, 2006, 2008, 2011).

Keeping the above perspective in mind, the present investigation was undertaken to evaluate the flocculation characteristics of the graft copolymers. The graft copolymers based flocculants have been prepared by using potassium persulphate (KPS) initiator solution methods of graft copolymerization of polyacrylamide onto polysaccharide backbones (starch, guar gum and amylose) in our laboratory. The synthesized graft copolymers have been characterized using various instrumental methods of analysis. The effects of various synthetic flocculants and their concentrations in combination with the coagulants on coagulation/flocculation of bentonite based drilling fluid waste have been studied. The effects of coagulant/flocculant dosage, salts concentration and pH on the degree of flocculation of bentonite based drilling fluid waste have been investigated.

Materials and Methods

Materials

Starch, amylose, guar gum, hydroquinone, potassium persulphate ($\text{K}_2\text{O}_2\text{S}_8$) were procured from Loba Chemie, Mumbai, India. Acetone, hydrochloric acid (HCl), sodium hydroxide (NaOH), sodium chloride (NaCl), aluminium sulfate ($\text{Al}_2(\text{SO}_4)_3 \cdot 16\text{H}_2\text{O}$), acrylamide were procured from Merck Life Science Private Limited Mumbai, India. Polyacrylamide (PAM) was obtained from Merck, Germany. Drilling fluid waste sample was collected from oilfield Kadi, Oil & Natural Gas Corporation Limited (ONGC) Ahmedabad Gujarat, India (Fig. 1). The zeta potential of the drilling fluid waste sample was found to be -23.1 mV at pH 4.

Synthesis of Graft Copolymers

The graft copolymers of starch, amylose and guar gum has been synthesized in inert atmospheric of nitrogen using potassium persulphate (KPS) as initiator. During synthesis 1 gm of starch/amylose/guar gum were slowly dissolved into 80 ml double distilled water in a three necked round bottom flask. The flask was fitted with an electrically operated magnetic stirrer (REMI, Model-2 MLH Magnetic Stirrer) and kept in water bath maintained at a temperature of $75 \pm 1^\circ\text{C}$ with constant stirring speed of 250 rpm. The reaction set up for graft copolymerization is shown in Fig. 2. Then nitrogen gas was purged for 15 min: afterwards, 0.1 gm of KPS was dissolved in 10 ml double distilled water and added to the solution. Then after 15 min the desired quantity of acrylamide (Table 3) dissolved in 50 ml double distilled water was poured slowly to the homogenous solution. The reaction was continued for another one hour under at $75 \pm 1^\circ\text{C}$ with stirring speed of 250 rpm. The reaction was terminated by addition of hydroquinone solution. The reaction was continued under continuous nitrogen gas purging from its initial reaction to final reaction. The reaction mixture was cooled to room temperature and the product was precipitated with acetone. Afterwards, it was dried in a hot oven at 55°C for 24 h, pulverized by mortar pestle and sieved through 100 mesh screens. The synthesis parameters are reported in Table 3. Synthetic details of graft copolymers are given below:

- St-g-PAM-I: Starch grafted polyacrylamide (8 gm of acrylamide, 1 gm of starch)
- St-g-PAM-II: Starch grafted polyacrylamide (15 gm of acrylamide, 1 gm of starch)
- Am-g-PAM-I: Amylose grafted polyacrylamide (8 gm of acrylamide, 1 gm of amylose)
- Am-g-PAM-II: Amylose grafted polyacrylamide (15 gm of acrylamide, 1 gm of amylose)
- Gr-g-PAM-I: Guar gum grafted polyacrylamide (8 gm of acrylamide, 1 gm of guar gum)

Fig. 2 Reaction set up for graft copolymerization.

Characterization of Graft Copolymers

Intrinsic Viscosity Measurement

Viscosity measurement of polymer solutions was carried out with the help of Ubbelohde viscometer (Constant: 0.003867) at 25°C. The viscosities were measured in dilute aqueous solution. The pH of the aqueous solution was neutral. The time of flow for solutions was measured at five different concentrations. From the time of flow of polymer solution (t) and that of the solution (t_0 , distilled water), relative viscosity ($\eta_{rel} = t/t_0$) was obtained. Specific viscosity was calculated from the relation, $\eta_{sp} = \eta_{rel} - 1$.

Table 3 Synthetic details of graft copolymers

Graft copolymer	Polysaccharides (gm)	Acrylamide (gm)	Amount of KPS (gm)	% Conversion	Intrinsic viscosity $[\eta](\text{dl g}^{-1})$	$M_n \times 10^6$	$M_w \times 10^6$
St-g-PAM-I	1	8	0.1	93	1.48	0.118	0.290
St-g-PAM-II	1	15	0.1	97	1.42	0.112	0.275
Am-g-PAM-I	1	8	0.1	92.8	1.07	0.072	0.193
Am-g-PAM-II	1	15	0.1	99.63	1.35	0.107	0.258
Gr-g-PAM-I	1	8	0.1	94	1.88	0.332	0.391

**Fig. 3** Reduced and inherent viscosity vs concentration curve for measurement of intrinsic viscosity of St-g-PAM-I.

Then, the reduced viscosity (η_{sp}/C), and the inherent viscosity ($\ln \eta_{rel}/C$) were calculated, Where, C is the polymer concentration in g/dl. The intrinsic viscosity was obtained from the point of intersection after extrapolation of two plots (Collins *et al.*, 1973; Tripathy *et al.*, 2000; Pal *et al.*, 2006), i.e., η_{sp}/C versus C and $\ln \eta_{rel}/C$ versus C , to zero concentration (as shown in Fig. 3). The intrinsic viscosity values of various polysaccharides grafted copolymers are listed in Table 3.

XRD Analysis

The synthesized graft copolymers were characterized X-ray diffraction (XRD) analysis to determine the qualitative mineral contents in the samples. XRD analyses were carried out using Philips PW 1040 Model diffractometer with Cu target at voltage 30 kV, current of 10 mA. The scattering angle (2θ) was varied from 0 to 80° .

FTIR Spectroscopy

FTIR spectra of various polymer samples were recorded using Perkin Elmer model Spectrum Two (USA) and range of the above measurements was $500\text{--}4000\text{ cm}^{-1}$. 1 mg of sample was mixed with a very small amount of KBr and KBr pellets were prepared using a hydraulic press by applying a pressure of 100 psi for the 60 s. The IR spectrums of the KBr pellets were recorded and 100 scans were collected.

Scanning Electron Microscopy (SEM) Analysis

The morphologies of the various polymer samples used in this study were analysed using ZESIS Model EVO 60 (Curl ZESIS SMT, Germany) with Air Lock chamber to examine the morphology of different polymers samples. The samples were charged with platinum coating to get clearer images. The elemental analyses of graft copolymers were carried out using Energy dispersive X-ray spectroscopy (EDX analyzer). The Scanning Electron Microscope (SEM) couple with Energy Dispersive X-ray Spectroscopy (EDX

Table 4 Elemental analysis results of starch, amylose, acrylamide, polyacrylamide and graft copolymers

Polymer	Carbon (wt%)	Oxygen (wt%)	Nitrogen (wt%)

Gr-g-PAM-I	51.00	33.86	15.14

analyzer) was used to determine the elemental composition of the above samples. The estimation of carbon, oxygen and nitrogen, was undertaken. The results are shown in [Table 4](#).

Flocculation Studies of Drilling Fluid Waste

The flocculation studies of various polymers were carried out using standard jar test methods ([Bratby, 1980](#); [Singh et al., 2000](#)). The apparatus contained six spindles with the blades (length 46 mm, width 17 mm, and thickness 3 mm) and variable speed ranging from 0 to 200 rpm with digital display. Each spindle is connected simultaneously by a series of stirrers connected with an electric motor through gears. The drilling fluid waste was diluted using distilled water (50% v/v). The adjustment of pH ranging from 4 to 10 was made by adding hydrochloric acid or sodium hydroxide (0.1 M HCl or 0.1 M NaOH concentration). The pH values of the samples were measured using a digital pH meter (Model 802, Systronics Ahmedabad, India). Afterwards, the diluted samples were put into 500 ml glass beakers. Required quantities of coagulant/flocculants/NaCl (0.001–0.1 M) were added from the top of the jar, and stirring speed was controlled by speed selector switch. The solution was mixed rapidly by increasing the speed (75 rpm) of stirrer for 1–2 min. After this rapid mixing, the solution was subjected to slow mixing (20–25 rpm) for 10 min. Finally, the flocs formed were allowed to settle for a period of 25 min.

Turbidity Measurements

After the settling of the flocs, supernatant liquid was carefully withdrawn from the top of the jar for the turbidity measurements using a syringe. The turbidity values were recorded in Nephelometric Turbidity Units (NTU) using a digital turbidity meter (Model 331E, Electronics Kolkata, India). Determination of total solid (TS), total dissolved solid (TDS) and total suspended solid (TSS) in the drilling fluid wastes were carried out gravimetrically ([Greenberg, 1999](#)).

Colour Removal Study

The colour removal study was carried out of oilfield drilling fluid waste by using synthesized graft copolymers. The detail experimental procedure was as follows; 100 ml of diluted drilling fluid waste was taken in 250 ml beaker and stirred by a magnetic stirrer (REMI, Model-2 MLH Magnetic Stirrer) at 300 rpm with 10 ppm polymer solution and varying NaCl concentration or pH for 30 min at room temperature. The solution was allowed to settle for 25 min and the supernatant liquid was collected from the top layer by syringe ([Kolya et al., 2017](#)). The colour measurement of the treated and untreated drilling fluid waste samples has been determined and represented graphically (absorbance versus wavelength) using UV-Visible Spectrophotometer (Thermo Scientific, Model: EVOLUTION 201).

Results and Discussions

Synthesis

The graft copolymers were synthesized using potassium persulfate (KPS) as a free radical initiator in nitrogen atmospheric, maintaining the reaction temperature at $75 \pm 1^\circ\text{C}$. Monomer (acrylamide), initiator, and 2.5 g of polysaccharides Starch/Amylose/Guar gum were used to synthesize the graft copolymers. Initially, the amount of monomer and polysaccharide were taken as 20.0 g and 2.5 g respectively, and were dissolved in 80 ml and 50 ml double distilled water respectively. But, due to high viscosity of the solution, the graft copolymerization could not be performed properly when the initiator was added to the solution. It was also observed the reaction product broke up while washing with acetone. The probable reasons were that the higher concentration of monomer resulted in the formation of undesirable homopolymers and higher concentration of polysaccharides resulted in higher viscosity of the solution. The above phenomenon caused hindrance in normal graft copolymerization by restricting the movement

of free radicals resulting in a less efficient initiation process and grafting efficiency (Ogbeifun and Okieimen, 2004; Pandey and Mishra, 2011; Maia *et al.*, 2012). Finally, the amount of monomer and polysaccharides were reduced to optimum concentrations (1.0 g of polysaccharides and 8.0/15.0 of monomer) considering its suitability for high grafting efficiency. The probable mechanism in the synthesis of graft copolymer was based on the generation of free radical sides on the backbone of biopolymer by KPS, which in turn reacted with the monomer (acrylamide) to form graft copolymer through initiation, propagation and termination (Jain *et al.*, 2014, 2017).

Calculation of the Approximate Molecular Weight

Molecular weight of the polymer samples can be estimated from the intrinsic viscosity $[\eta]$ values. The Mark- Houwink equation, $[\eta] = KM^\alpha$ is generally employed for the estimation of molecular weight of linear polymers, where K and α are constant. For a given polymer/solvent/temperature system. For polyacrylamide the value of K and α are given below (Mendelson, 1969; Erciyes *et al.*, 1992; Karmakar and Singh, 1998; Tripathy *et al.*, 2000; Biswal and Singh, 2004).

$$[\eta] = 6.8 \times 10^{-4} (M_n)^{0.66} \quad (1)$$

$$[\eta] = 6.31 \times 10^{-5} (M_w)^{0.80} \quad (2)$$

Where, M_n is the number-average molecular weight and M_w is the weight-average molecular weight. Several workers (Erciyes *et al.*, 1992; Karmakar and Singh, 1998; Tripathy *et al.*, 2000; Biswal and Singh, 2004) have been used the Mark- Houwink equation to estimate approximate molecular weight, which is applicable for linear polymers. The same has been done in the present case. The estimate approximate molecular weight of the graft copolymers are given in Table 3.

$$\% \text{ Conversion} = \left(\frac{\text{Wt. of graft copolymer} - \text{Wt. of polysaccharide}}{\text{Wt. of acrylamide monomer}} \right) * 100 \quad (3)$$

X-ray Diffraction Analysis

X-ray diffraction pattern of all the polysaccharides grafted copolymers (St-g-PAM-I to Am-g-PAM-II) are shown in Fig. 4. In this pattern of XRD analysis, all graft copolymers do not show single peak indicating crystallinity in between a range of 2θ (21–45°). The X-ray diffraction patterns also do not show a sharp peak. However, the grafted products do not indicate any crystallinity or any

Fig. 4 X-ray diffraction pattern of graft copolymer (A) St-g-PAM-I, (B) St-g-PAM-II, (C) Am-g-PAM-I, (D) Am-g-PAM-II.

Fig. 5 FTIR spectra of graft copolymer (A) St-g-PAM-I, (B) St-g-PAM-II.

Fig. 6 FTIR spectra of graft copolymer (A) Am-g-PAM-I, (B) Am-g-PAM-II.

sharp peak due to acrylamide monomer. Similar results have also been obtained from the analysis of grafted products synthesized by earlier workers using the same method (Tripathy *et al.*, 1999; Biswal and Singh, 2006).

FTIR Analysis

The FTIR spectra of polysaccharides grafted copolymers (St-g-PAM-I, St-g-PAM-II, Am-g-PAM-I and Gr-g-PAM-I) are shown in Figs. 5(A) and 6(B). The spectrum of St-g-PAM-I (Fig. 5(A)) displays a broad absorption band at 2983 cm^{-1} , 2813 cm^{-1} , and 2513 cm^{-1} are due to N-H, C-H and O-H groups stretching vibration. The bands at 1975 cm^{-1} and 1492 cm^{-1} belong to

C=C and N-O groups stretching vibration. The bands at 1188 cm^{-1} and 1064 cm^{-1} belong to C-O group stretching vibration, but the bands at 915 cm^{-1} and 752 cm^{-1} belong to C=C and O-H group bending vibration. In case of St-g-PAM-II (Fig. 5(B)), the stretching vibration are due to C-H group at 2983 cm^{-1} and 2819 cm^{-1} respectively. The bands at 2499 cm^{-1} and 2049 cm^{-1} belong to S-H and N=C=S groups stretching vibration. But, the medium absorption bands at 1486 cm^{-1} and 1369 cm^{-1} belong to C-H or O-H groups are due to bending vibration. Again, the strong absorption bands at 1157 cm^{-1} , 906 cm^{-1} and 751 cm^{-1} are the stretching or bending vibration in the presence of C-O, C=C and C-H groups.

Fig. 6(A) shows the FTIR spectrum of Am-g-PAM-I. The medium absorption bands at 2985 cm^{-1} and 2818 cm^{-1} are due to C-H stretching vibrations. The presence of a weak and strong band absorption at 2493 cm^{-1} and 2036 cm^{-1} confirms the presence of S-H and N=C=S groups respectively. But, the bands at 1484 cm^{-1} , 906 cm^{-1} and 740 cm^{-1} are assigned to C-H, C=C and C-H groups bending vibration. The strong band absorptions at 1151 cm^{-1} and 578 cm^{-1} are due to C-O and C-I groups stretching vibrations. Finally, in the spectrum of Am-g-PAM-II (Fig. 6(B)) a broad medium absorption bands at 2985 cm^{-1} and 2818 cm^{-1} are stretch for C-H group. The bands at 2498 cm^{-1} and 2044 cm^{-1} are represents stretching vibration of S-H and N=C=S groups respectively. The bands around at 1484 cm^{-1} , 1369 cm^{-1} are assigned to C-H group and at 915 cm^{-1} is confirms due to C=C group bending vibration. But, the bands at 1151 cm^{-1} and 573 cm^{-1} are a typical stretch of C-O and C-I groups.

Scanning Electron Microscopy (SEM) Analysis

The scanning electron microscopy (SEM) was used to investigate the surface morphological feature of starch, amylose and synthesized graft copolymers (St-g-PAM-I and Am-g-PAM-I) with acrylamide. The morphological feature of starch shows cohesive and dense structure (Fig. 7(A)). The morphological feature of amylose is a smooth and continuous surface and granular structure with no distinct perturbations (Fig. 7(B)). After grafting the granular appearance of starch and amylose were distorted and changed to fibrillar. The morphology of acrylamide has also found to be changed after grafting with starch and amylose (Fig. 8). The SEM micrograph of graft copolymer St-g-PAM-I and Am-g-PAM-I showed that the graft copolymerization of starch and amylose with acrylamide dramatically changed the conformation of polysaccharides polymer (starch and amylose) chain. The similar morphological structure changes were also observed by earlier workers while performing the graft copolymerization using chitosan and polyacrylamide (Soliman *et al.*, 2014). This observation suggests that the grafting of acrylamide affects the morphological arrangement of polymers. The micrograph of graft copolymers showed a number of long chain of acrylamide which got agglomerated and changed in fibrillar structure (Fig. 9(A) and (B)) (Jain *et al.*, 2017).

Flocculation Characteristics

The drilling fluid waste sample collected from Kadi, ONGC Ahmedabad, Gujarat was treated for coagulation and flocculation studies. The initial pH of the waste was 8.25, the turbidity value was 1589 NTU. While treating the waste, it was observed that it was very difficult to treat the waste with either alum or polymer alone by coagulation or flocculation. The concentrated solutions (90% volume of drilling fluid waste along with 10% volume of distilled water) could not be treated effectively. This was due to the fact that the oilfield drilling waste mainly contained lignosulfonates, lignin, solid drill cuttings, and high molecular weight polymeric compounds. The plastic and the apparent viscosity of the drilling fluid wastes were also high. It was difficult to

Fig. 7 Scanning electron micrograph of (A) starch, (B) amylose.

flocculate the particles with polymeric flocculants alone. Therefore, the original waste was diluted with the addition of equivalent amount of distilled water. Afterwards, it was coagulated with coagulant $\text{Al}_2(\text{SO}_4)_3 \cdot 16\text{H}_2\text{O}$ and then flocculated with grafted copolymers. Standard jar test method was followed for flocculation and the supernatant turbidity values in NTU were measured after specific settling period after flocculation. **Fig. 10** showed that untreated drilling fluid waste sample before flocculation test and after flocculation test.

Effect of flocculants

The diluted drilling fluid waste was first coagulated with $\text{Al}_2(\text{SO}_4)_3 \cdot 16\text{H}_2\text{O}$ by fast mixing at 75 rpm for one minute. Then flocculants (graft copolymers) were added and stirrer for one more minute. Subsequently, it was subjected to slow mixing at 20 rpm for 10 min and settling for 25 min. Initially, the 10 ppm concentration of polyacrylamide/graft copolymer was fixed while varying the alum concentration from 10 ppm to 80 ppm. Increasing the alum concentration resulted in decreasing the turbidity of the waste up to a certain concentration of the alum. Further increase in alum concentration resulted in increasing the turbidity value. The turbidity value of the supernatant liquid was recorded 320 NTU at 40 ppm and then further increase in alum concentration resulted in restabilization of the particles showing the turbidity value of 546 NTU at 80 ppm. Hence, 40 ppm of alum concentration was fixed while varying the graft copolymer concentrations from 10 ppm to 50 ppm for the next set of experiments. It was observed that when the polymer concentration increased from 10 ppm to 30 ppm the turbidity value of supernatant liquid decreased from 224 NTU to 201 NTU. Further increase in the concentration of graft copolymer up to 50 ppm, the turbidity value of supernatant liquid increased from 304 NTU to 384 NTU (St-g-PAM-I). The turbidity value was found to be lowest 201 NTU when 30 ppm of the Am-g-PAM-II polymer was used. The results of flocculation performance above grafted

Fig. 10 (A) Untreated drilling fluid waste, (B) Treated drilling fluid waste.

Fig. 11 Comparison of flocculation performance of grafted copolymers in oilfield drilling fluid waste.

copolymers are given in Fig. 11. It is clearly indicated that the Am-g-PAM-II had shown better flocculation performance (Table 5) in comparison with other graft copolymers and commercial (PAM) flocculants.

Effect of NaCl concentration

A series of coagulation-flocculation tests were carried out with varying NaCl concentration (0.001 M, 0.01 M, 0.05 M and 0.1 M) while fixing the concentration of alum at 40 ppm and the concentration of graft copolymers at 10 ppm. The supernatant turbidity values in NTU were recorded as a function of NaCl concentration of the system. The results are given in Fig. 12. It was found that the supernatant turbidity values decreased when the NaCl concentration of the system was more than 0.05 M. The drilling fluid waste was highly flocculated in the interval of 0.05–0.1 M of NaCl concentration. The flocculation of the waste with NaCl concentration < 0.001 M resulted in deflocculation which showed high values of supernatant turbidity. Using 10 ppm of Am-g-PAM-II graft copolymer it was observed that when the NaCl concentration of the system was increased from 0.001 M to 0.1 M the supernatant turbidity value was decreased from 216 NTU to 177 NTU. It was clear that the supernatant turbidity value was decreased to about 47.75% with 0.1 M NaCl concentration at 10 ppm of the graft copolymer (Am-g-PAM-II). This was the higher percentage of turbidity reduction compared to other graft copolymers. The results are plotted in Fig. 12. It was observed that the polysaccharide grafted copolymers (Am-g-PAM-II) had shown better flocculation performance in presence of NaCl solution.

Table 5 Flocculation performance of the graft copolymers in oilfield drilling fluid waste

Polymer	Turbidity value (NTU)	TS (ppm)	TDS (ppm)	TSS (ppm)
Without polymer	772	126	81	45
PAM	430	40.82	37.08	3.74
St-g-PAM-I	320	33.00	28.32	4.68
St-g-PAM-II	304	29.70	26.56	3.14
Am-g-PAM-I	311	37.22	39.97	4.25
Am-g-PAM-II	224	17.22	14.00	3.22
Gr-g-PAM-I	315	22.28	19.07	3.21

**Fig. 12** Effect of NaCl concentration (M) on supernatant turbidity value.

Effect of pH suspension

As discussed earlier, for effective flocculation the drilling fluid waste was diluted with addition of equivalent amount of distilled water. The pH of the system was adjusted by adding hydrochloric acid or sodium hydroxide (0.1 M HCl/0.1 M NaOH concentration). The coagulation-flocculation studies were carried out using 40 ppm of alum and 10 ppm of graft copolymer/polyacrylamide using standard jar test method. After flocculation, the turbidity values of the supernatant liquids were determined under various pH conditions. The supernatant turbidity values in NTU were recorded as a function of pH of the system. The results are presented in Fig. 13. It was observed that as the pH value of the system increased the supernatant turbidity value decreased. This was due to increase in the +ve charge density of the ions present in alkaline media (at pH 9). The attraction between the positively charged ions and negatively charged hydroxyl groups of the alkali enhanced the aggregation of the particles. The turbidity value of the supernatant liquid was recorded highest at 420 NTU using 10 ppm of PAM at pH 4 of the system. It also was found that the turbidity value was lowest at 204 NTU using 10 ppm of Am-g-PAM-II at pH 10 of the system. Finally, it was observed that at pH 10, Am-g-PAM-II was the most effective flocculant for the above system.

Colour Removal Study

The colour removal study of the oilfield drilling fluid waste effluent by the five polysaccharides grafted copolymers were carried out in a UV-Visible Spectrophotometer under optimum condition (polymer dose 10 ppm varying pH or NaCl concentration, time 30 min and room temperature). The UV-Visible results were shown in Figs. 14–16. The comparison was carried out among polysaccharides grafted copolymers (St-g-PAM-I, St-g-PAM-II, Am-g-PAM-I, Am-g-PAM-II and Gr-g-PAM-I). It was obvious from Fig. 14 that polysaccharides grafted copolymer (St-g-PAM-I) showed a better colour removal performance

Fig. 13 Effect of pH on supernatant turbidity value.

Fig. 14 Colour removal characteristics of polysaccharide grafted copolymers in drilling fluid waste.

compared to other grafted copolymers. In this case, the colour removal efficiency was compared by the absorbance value at $\lambda_{\max}$ 560 nm. The absorbance values were lower, showing that higher will be the colour removal efficient. The performance of grafted polysaccharides copolymer (St-g-PAM-I) was also explanted at varying NaCl concentration and pH of suspension. It was found to be the performance of St-g-PAM-I at pH 4 was better compared to the other pH of suspension for colour removal efficiency. The result was shown in Fig. 15. It was also obvious from in Fig. 16 that at NaCl concentration 0.01 M the polysaccharides grafted copolymer (St-g-PAM-I) had a better performing for colour removal than compared to other concentration of NaCl.

Fig. 15 Colour removal characteristics of St-g-PAM-I at varying pH in drilling fluid waste.

Fig. 16 Colour removal characteristics of St-g-PAM-I at varying NaCl concentration in drilling fluid waste.

Conclusions

- (1) Grafting of acrylamide monomer on starch, amylose and guar gum polysaccharide backbones were successfully carried out using potassium persulphate (KPS) as an initiator.
- (2) The synthesis of the above graft copolymers were confirmed by the instrumental analyses of their products.
- (3) The Am-g-PAM-II had shown better flocculation performance in comparison with other graft copolymers and commercial flocculants (PAM) for the bentonite suspension.

- (4) While treating the drilling fluid waste, it was observed that neither a coagulant nor a flocculant alone could completely flocculate such complex systems. After destabilizing such wastes with a suitable coagulant, polysaccharide grafted polymers could be used as flocculant aids for the complete flocculation of the contaminants present in the systems.
- (5) Polysaccharide based grafted copolymers were found to be efficient flocculants aids for treatment of the drilling fluid wastes in presence of NaCl and at higher pH conditions.
- (6) The polysaccharide based grafted copolymer (St-g-PAM-I) have a better performing for colour removal efficiency than compared to other grafted copolymers.

Acknowledgements

We are thankful for Oil and Natural Gas Corporation Limited (ONGC), Ahmedabad Gujarat, India for providing oilfield drilling fluid waste sample. We also thank Prof. K. Pathak, Department Mining Engineering IIT Kharagpur for providing the laboratory for personal help, which has been helpful for my research work.

Introduction

The history of natural colorants or dyes goes back many hundreds of years. For example, indigo (Fig. 1) has been known for more than 5000 years and catechu has been in use as a brown colorant in India for over 2000 years (Wickens, 1983). Different natural sources of colorants such as flowering plants, fungi, lichens, insects, shellfish, and various earth minerals are available around us. They have found applications in the areas of food, pharmaceutical, dye sensitized solar cells, tanning, pH indicator, agriculture, textiles, cosmetics, and fragrance (Adeel *et al.*, 2017). This article gives an overview of the natural colorants for textile applications. Cannon and Cannon (2002) presented a list of 47 flowering plants that have been historically used in textile dyeing in their book *Dye Plants and Dyeing*. Different parts of these plants including leaves, flowers, fruits, seeds, barks, and roots contain coloring materials that can produce different shades on textiles. Natural colorants were used solely for textile coloration until 1856, when an 18-year-old British man named William Henry Perkin accidentally synthesized a purple colorant from aniline, one of the simplest chemical components of coal tar, while experimenting to synthesize the antimalarial drug quinine, and found that his colorant could readily dye silk material (Openlearn, 2007).

Classification of Natural Colorants

The colorants that come from nature can be classified in a number of ways, such as, based on their origins, chemistry, application methods, and the main hues they produce (see Fig. 2).

Natural colorants can be derived from plants, insects/animals, and minerals (Patel, 2011) as shown in Fig. 3. Extract from various parts of plants and herbs including the stem, wood, roots, bark, leaves, flowers, and fruits can produce distinct pale to dark shades on both natural or synthetic fibers; for example, logwood, turmeric, pine wood, catechu, madder, etc. From the animal kingdom, the exudation of dried bodies of a few insects and mollusks can act as coloring substances. For example, the colorants carminic acid, kermesic acid, and accaic acid come from the dried bodies of cochineal, kermes, and lac respectively (Yusuf *et al.*, 2017). Some natural colorants are obtained from mineral sources. For example, red ocher and yellow ocher are two clay earth pigments that occur naturally as minerals.

Plant-based natural colorants, which are known for their medicinal and herbal applications, are mainly phenolic compounds (Alihosseni and Sun, 2011). Flavonoids are one of the most abundant colorants found in flowers, leaves, fruits, and seeds and they make up almost 50% of all the natural colorants used for textiles and listed in the color index (Alihosseni and Sun, 2011). The major dye classes within the family of flavonoids are flavones and flavonols, and the predominant flavonols in nature are

Fig. 2 Different classifications of natural colorants. Modified from Yusuf, M., Shabbir, M., Mohammad, F., 2017. Natural colorants: Historical, processing and sustainable prospects. *Natural Products and Bioprospecting* 7, 123–145, doi:10.1007/s13659-017-0119-9.

Fig. 3 Main sources of natural colorants.

quercetin (Fig. 4) and kaemferol (Alihosseni and Sun, 2011). Flavonoids have been identified as having antioxidant, anti-inflammatory, antiallergic, anticarcinogenic, and antimicrobial functions (Sarkar and Dhandapani, 2009).

Natural colorants from different sources impart different colors on textile substrates. Tables 1 and 2 present a list of common natural colorants from various sources together with their hues and chemical classes (Table 3).

Coloration Techniques

Although a few natural dyes are substantive (or direct or nonmordant) dyes, for example walnuts and onion skins, a majority of them require helping chemicals to promote their absorption into and fixation with textile fibers. They are collectively known as adjective or mordant dyes and the helping chemicals are known as mordants, which work by forming chemical bonds between the dye molecules and fiber polymer. Some mordants can be natural substances, for example, urine, wood ash, plants galls, tannins, and crabapple juice, whereas some are pure chemical compounds with metallic ions. These chemical compounds are commonly salts of aluminum (potash alum – potassium aluminum sulfate, ammonia alum – ammonium aluminum sulfate), chromium (potassium dichromate), iron (ferrous sulfate), tin (stannous chloride), and copper (copper sulfate). In textile dyeing, mordant

Name of colorant	Scientific name	Colorant extracted from	Hue	Chemical class	References
Cochineal	<i>Coccus cacti</i>	Dried body	Crimson, scarlet and pink	Quinonoid	Patel (2011), Yusuf <i>et al.</i> (2017)
Lac	<i>Laccifer lacca</i>	Dried body	Red, scarlet, brown	Quinonoid	Patel (2011), Vankar (2000), Yusuf <i>et al.</i> (2017)
Kermes	<i>Kermes vermilio</i>	Dried body	Red, purple	Quinonoid	Patel (2011), Yusuf <i>et al.</i> (2017)

can be used before, during, or after the dyeing process, therefore the techniques are known as premordanting, simultaneous mordanting, or postmordanting respectively.

Printing with natural dyes varies according to the use of mordant and thickener combination in print paste. For printing, extracted dye liquor is made concentrated by boiling and combining with thickener, and applied mostly on premordanted fabric. Print paste may also be prepared by combining mordant with natural dyes and thickener and applied on scoured or bleached fabric. Printing is usually done by flat screen print or batik printing methods.

Research and Innovations

The advent of synthetic dyes has hindered the use of natural colorants over centuries as the synthetic dyes have become widely available and they exhibit better fastness properties with good reproducibility. However, there is a growing interest in research surrounding the use of natural dyes for textiles because of the environmental impact of the production and use of synthetic colorants. Fig. 5 represents the potential applications of natural dyes in textiles.

Table 3 Examples of natural colorants from mineral origin

Name of colorant	Colorant extracted from	Hue	Chemical class
Cinnabar or sulfide of mercury	Dust	Scarlet, brick red	Mercury sulfide
Red Ocherochre	Dust	Yellow to deep orange, brown	Anhydrous and hydrated iron oxide ($\text{Fe}_2\text{O}_3 \cdot n\text{H}_2\text{O}$)
Red lead	Dust	Bright red	Lead oxide
Yellow Ocherochre	Dust	Yellow	Limonite/hydrated ferric oxide ($\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$)
Sienna	Dust	Yellow	Iron oxide and manganese oxide
Orpiment	Dust	Lemon yellow	Arsenic sulfide
Litharge	Dust	Pale yellow	Lead oxide
Green earth	Dust	Yellow green to greenish gray	Mixture of hydrosilicates of Fe, Mg, Al, and K (glauconite and celadonite)
Malachite	Dust	Green	Copper carbonate hydroxide
Verdigris	Dust	Bright and deep green	Acetate of copper
Ultramarine blue (lapis lazuli)	Stone dust	Deep blue	Lazurite
Azurite	Dust	Blue	Copper carbonate hydroxide
White lime	Dust	White	Calcium carbonate
White lead	Dust	White	Carbonate and hydroxide of lead
Zinc white	Dust	White	Zinc oxide
Charcoal black	Powdered after burning in a close pot	Black	Lightweight black carbon and ash residue hydrocarbon
Graphite	Dust	Dull gray	Allotrope of carbon
Black clay	Dust	Black	Carbonate of calcium, iron, and manganese with clay
Black earth	Dust	Black	Carbonate of calcium, iron, and manganese with clay

Note: Produced based on and adapted from Yusuf, M., Shabbir, M., Mohammad, F., 2017. Natural colorants: Historical, processing and sustainable prospects. *Natural Products and Bioprospecting* 7, 123–145, doi:10.1007/s13659-017-0119-9.

**Fig. 5** Various applications of natural colorants in textiles.

Currently research activities are being undertaken around the world on a number of topics including chemistry of natural dyes, extraction of colorant from new sources, interaction of mordants, natural dyes and textiles, optimization of dye extraction, mordanting, and dyeing methods (Samanta *et al.*, 2018). An overview of the recent research and innovations related to the renewable natural colorants is provided in the following subsections.

Extraction and Traditional Dyeing With Natural Dyes

Efficiency of extraction of natural dyes largely depends on the type of sources and various processing variables such as pH, temperature, time, liquor ratio, and particle size. The methods of extraction of natural dyes can be classified based on the media

used in extraction, such as aqueous, nonaqueous, organic, and mixture of aqueous–organic extraction. This may be performed in varying pH, temperature, and duration. Extraction of colorant from aqueous solution of the flower petals of the “flame of forests” (*Butea monosperma*) has been performed at varying process conditions and the optimum condition was reported as around 74°C temperature and 154 min of duration (Sinha *et al.*, 2012). The efficiency of extraction was found to be 8813.67 mg/L. Dayal and Dobhal (2001) successfully extracted aqueous solution from the leaves of eucalyptus hybrid and seeds of *Cassia tora* and *Grewia optiva*. There are also reports on potential use of natural dyes extracted by aqueous medium from different plant sources, for example coffee seed (*Coffea*), tea (*Camellia sinensis*), onions (*Allium cepa*), tamarind (*Tamarindus indica*), henna (*Lawsonia inermis*), lemongrass (*Cymbopogon citratus*), cardamom (*Elettaria cardamomum*), beetroot (*Beta vulgaris*), sandalwood (*Santalum*), saffron (*Crocus sativus*), biomass precursors like cutch (*Senegalia catechu*), ratanjot (*Alkanna tinctoria*), and madder (*Rubia tinctorum*) (Teli and Paul, 2006; Tsatsaroni and Eleftheriadis, 2008; Khan *et al.*, 2006). Vankar *et al.* (2001) utilized supercritical CO₂ for the extraction and purification of colorant from eucalyptus bark. Ticha *et al.* (2017) isolated anthocyanins dyes using ultrasonic energy from the aqueous extract of fruits of *Parthenocissus quinquefolia*.

Natural dye isolated from cumin seeds (*Cuminum cyminum*) in different buffer mediums as acidic, neutral, and alkaline was applied successfully on premordanted and nonmordanted cotton fabric and compared with the commercial reactive dyes (Tayade and Adivarekar, 2013). Their report presented good potentiality of the natural dyes in terms of color yield, fastness quality, and economical for industrial application as compared with the regular synthetic dyes. Bleached and double premordanted jute fabric can be successfully dyed with single and binary mixtures of different aqueous isolation of red sandalwood (*Pterocarpus santalinus*), manjistha (*R. cordifolia*), jackfruit wood (*Artocarpus heterophyllus*), marigold (*Tagetes*), sappan wood (*Biancaea sappan*), and babool (*Vachellia nilotica*) (Samanta *et al.*, 2009).

Räisänen *et al.* (2001) dyed polyester and polyamide successfully with natural anthraquinones, isolated from fungus *Dermocybe sanguinea* as natural disperse dyes, at high temperature method and compared with an equivalent disperse dye. Natural anthraquinones are found to be useful alternatives to the existing synthetic disperse dyes offering bright hues with excellent colorfastness. Wool is found to be dyeable with yellow and red dyes extracted from the fungi *Penicillium murcianum* and *Talaromyces australis* respectively, which show great potential for commercialization (Hernández *et al.*, 2019).

Pretreatments, Modification, and Nontraditional Dyeing

Different technical pretreatments can be applied on textiles to improve the uptake of natural dyes into textiles during coloration processes. Maulik *et al.* (2011) modified cotton fabrics using acrylamide in presence of potassium peroxodisulfate (K₂S₂O₈) by graft copolymerization in pad-dry-cure technique to enhance dye uptake, tensile strength, wrinkle recovery angle, and overall fastness quality with tea (*C. sinensis*) and pomegranate (*Punica granatum*) dye extracts. They found that premordanting with ferrous sulfate following a presalt application of the modified cotton resulted in improved depth and all-round colorfastness.

Haji (2017) treated cotton fabric with low-pressure oxygen plasma and applied chitosan coating before dyeing with the extraction of pomegranate rinds. Plasma treatment was found to be effective in enhancing the color strength of dyed textile. At the same time, the fabric coated with chitosan and dyed with pomegranate extraction was also found to be functional against bacteria. Dayioglu *et al.* (2015) dyed silk with the fruit extraction of dwarf elder (*Sambucus ebulus* L) by conventional and microwave-assisted dyeing methods. They treated silk fabric with oxygen plasma prior to dyeing and found that the plasma treatment time and microwave energy contributed towards the increased dye diffusion into the silk polymer. Similar effect of plasma treatment on premordanted wool fabric prior to dyeing with Acacia plant extraction was reported by Ratnapandian *et al.* (2011).

An interesting procedure of gamma ray radiation on natural dye and cotton fabric prior to dyeing was reported by Khan *et al.* (2014). They exposed powder of red calico (*Alternanthera bitzickiana*) leaves to different doses of gamma radiation before extraction in aqueous, alcoholic, and alkaline media, and cotton fabric before mordanting and dyeing. According to them, cotton fabric after exposure to gamma radiation can be dyed with red calico extract using reduced the amount of mordants yielding high colorfastness properties.

Sonicator dyeing method has been successfully applied to improve dyeing performance of cationized cotton textile with red cabbage (*Brassica oleracea*) isolation (Ticha *et al.*, 2016). Several explorations on ultrasonic assisted dyeing that have been reported by far are cotton dyeing with neem (*Azadirachta indica*) leaf extraction (Senthilkumar *et al.*, 2002) and sappan wood (*Biancaea sappan*) extraction (Ghorpade *et al.*, 2000); dyeing of enzyme pretreated cotton with isolation from *Acacia catechu* and *Tectona grandis* (Vankar and Shanker, 2008); and wool dyeing with lac (Kamel *et al.*, 2005).

Functionalization and Value Addition by Dyeing With Natural Colorants

Selective natural colorants exhibit functional characteristics. Wool fabric dyed with the extraction from walnut hull (*Juglans regia*) and henna (*L. inermis*) was found to be effectively mothproof (Nazari, 2017). Silk fabric dyed with chemically modified water-soluble curcumin extracted from the root of *Curcuma longa* L was found to be UV protective in addition to having antibacterial functionality (Zhou and Tang, 2016).

Tannins extracted from *Dioscorea cirrhosa* tuber produce stunning shades on silk and the dyed fabric exhibits a number of functionalities like antibacterial and antioxidant activities (Yang *et al.*, 2018). Particularly condensed tannin coating including

postmordanting with iron salt enables the silk fabric to be flame retardant and waterproof. The findings from recent studies show that multifunctional textiles can be developed by using natural dyes in different methods on different substrates. For example, a multifunctional wool fabric developed from the extraction of *Lycium ruthenicum* Murray (Dong *et al.*, 2018), and antibacterial silk fabric dyed with isolation from red prickly pear fruit (*Opuntia ficus-indica*) (Ganesan and Karthik, 2017).

Printing With Natural Dyes

Several studies on printing of different textile fabrics with natural dyes have been reported in different literature (Salem *et al.*, 2013; Maamoun *et al.*, 2014; Rekaby *et al.*, 2009; Chattopadhyay and Pan, 2018). Polyester fabric can be printed with the extracts from different plants like turmeric (*Curcuma longa*), alkanet (*A. tinctoria*), and rhubarb (*Rheum rhabarbarum*) using natural and synthetic thickeners at various processing conditions of transfer printing, and satisfactory fastness properties can be achieved (Salem *et al.*, 2013). Cotton/wool blended fabric printed with nanoparticles of turmeric, madder, and rhubarb was found to have excellent wash, rubbing, and perspiration fastness (Maamoun *et al.*, 2014). Rekaby *et al.* (2009) applied different fixation techniques for cotton, wool, silk, and flax substrates printed with extracts of alkanet and rhubarb colorants. They found steam fixation provided better color strength (K/S) as compared with the thermofixation. Very good fastness with varying color yields were obtained with different mordants. Chattopadhyay and Pan (2018) attempted screen printing with the extracts from annatto (*Bixa Orellana*), roots of manjistha (*Rubia cordifolia*), and bark of ratanjot (*A. tinctoria*) of bioscoured, bleached, and premordanted jute fabrics and achieved very good wash and rubbing fastness properties.

Natural Versus Synthetic Colorants

Nowadays the use of natural dyes has attracted a lot of attention in the textile industry due to their eco-friendliness and renewable characteristics, and these colorants are gradually making their way into the global market. A number of other benefits of using natural dyes are highlighted in the literature (Samanta and Konar, 2011; Arora *et al.*, 2017). Natural dyes:

- Are biodegradable, nontoxic, and nonallergic.
- Have color shades usually soft, lustrous, and esthetically appealing to the human eye.
- Are widely available from natural sources such as plant (leaves, bark, flower, etc.), insect/animal, and mineral.
- Exhibit medicinal effects such as reduced chances of melanoma through absorption of UV, antiallergens, and antibacterial properties.

The use of natural dye can also bring some positive impacts to the environment and society in general such as:

- Earning carbon credit through reduction of petroleum based synthetic colorants.
- Creating job opportunities in cultivation, extraction, and application.
- Utilizing wasteland to cultivate the dye plants in a large scale.
- Disposing of natural dye waste in a simple and inexpensive way as biofertilizer for agriculture or the biomass for energy generation.
- Creating an overall sustainable system for the textile industry.

On the other hand, the synthetic colorants are nonrenewable, nonbiodegradable, sometimes carcinogenic, and cause water pollution, and produce toxic waste and present a huge challenge in disposing the byproduct waste in a cost effective way. However, some key benefits of synthetic colorants in terms of producing in large scale at economical price with consistent color quality and numerous color variation outweigh the benefits of natural dyes (Fig. 6). Therefore, the synthetic dye still remains as the prime choice for textile industry.

Challenges for Natural Dye in Commercial Use

The market for synthetic colorants is valued at around \$23 billion for a total production volume of approximately 1.3 million tonnes (Sengupta and Singh, 2003). It is estimated that only 1% of total world textiles are dyed with the natural colorants. This indicates that the natural colorant has to overcome a number of technical, logistical, and commercial challenges to enter into the mainstream textile processing. Fig. 7 summarizes some of the key challenges and potential solutions, which will also be elaborated briefly in the following subsections. Further details about the natural colorants and their future prospects can be found in the recent literature (Adeel *et al.*, 2019; Gürses, 2019; Arora *et al.*, 2017; Gürses *et al.*, 2016; Saxena and Raja, 2014; Shahid *et al.*, 2013; Samanta and Konar, 2011).

Technical Challenge: High Quality Dye Production

Plants, the major source of natural colorants, may vary from one season to another, one cultivating region to another, one soil quality to another, one agroclimate to another, high maturity to low, and one species to another, which causes variation in color

Fig. 6 Balance between natural and synthetic colorants.

Fig. 7 Challenges of natural colorants and possible solutions.

Fig. 8 Rainbow of textile dye colors from a variety of natural sources. Inspired from Arora, J., Agarwal, P., Gupta, G., 2017. Rainbow of natural dyes on textiles using plants extracts: Sustainable and eco-friendly processes. *Green and Sustainable Chemistry* 7, 35–47. Sims, A., 2018. 4 Steps to Naturally Dyeing Any Fabric Using Foods. Available at: <https://www.architecturaldigest.com/story/how-to-naturally-dye-using-foods> (downloaded April 8, 2019).

reproducibility of natural dye (Saxena and Raja, 2014). Poor color reproducibility could also result due to variations in conditions of dye extraction and dyeing. Therefore, dye extraction and dyeing methods must be optimized for specific dye–fiber–mordant combinations through scientific studies (Samanta *et al.*, 2018) to get the maximum color intensity with reproducible shades.

The traditional challenges of lack of color variations can be overcome by processing the dye from the same plant extract with different mordants, extraction mediums, and dyeing techniques (Arora *et al.*, 2017) as a mix and match system. An entire rainbow of colors could be created from different plant and biological sources as shown in Fig. 8. Again mixing of different compatible natural colorants in different quantities could produce a wide spectrum of color shades (Samanta *et al.*, 2018).

In general, low color yield of source plant materials restricts the availability of natural colorants in a large scale and thus more dyestuffs, longer dyeing time, and mordanting are required. Application of modern technologies such as ultrasonic, microwave, and enzyme assisted dye extraction can be adopted to improve dye yield (Samanta *et al.*, 2018). In future, dye yield can be significantly improved by biotechnological interventions such as genetic engineering (Saxena and Raja, 2014).

In the majority of the cases, environmentally unsound metal-based mordant or mordant assistant is required to fix the natural dye onto the fabric. During the dyeing process, a part of the mordant is left unexhausted in the residual dye bath and this may cause serious effluent disposal problems (Saxena and Raja, 2014). Metal-based mordants can be replaced by suitable biobased mordants to reduce the environmental impact.

Colorfastness on exposure to lighting, washing, contact with human perspiration, and rubbing of natural dye is relatively poor compared with synthetic dye. Pretreatments and posttreatments have been successfully applied to improve the color fastness properties of synthetic dyed textiles. However, treatments for natural dyed textiles are limited (Khan *et al.*, 2014) and therefore new fastness improved from natural materials needs to be explored (Samanta *et al.*, 2018). Standardization and optimization of mordanting and dyeing procedures can improve the poor colorfastness issue (Saxena and Raja, 2014). New sources of dye extracting plants with improved colorfastness properties also need to be explored.

Logistical Challenge: Availability in Large Quantity

As a rule of thumb, 1 kg of dye plant is required to dye 1 kg of textile. The plants contain natural dye in small quantity. Therefore, to meet the current dye demand of massive quantity, it would require a huge amount of plants, which nature simply cannot provide and thus necessitates cultivation of dye extracting plants. Again, land for growing food crops cannot be used for this purpose as meeting the continuously growing demand of food crops for the increasing world population is far

more important than cultivation of dye extracting plants. However, the plants can be grown in wastelands to increase their availability. Some of the colorants are obtained from tree bark, roots, and stems, which again cannot be obtained without damaging the tree. Although agricultural by-products such as pomegranate rind, onion skin, or fruits and leaves of trees are available at the farm or point of use, no logistics for making them available for dye production are in place. Therefore, a large supply chain network for agrobased byproducts needs to be established to enhance the availability of dye containing raw materials (Saxena and Raja, 2014). Extracting dye as a byproduct from the timber industry is sustainable but cutting trees only for dye extraction would lead to a serious problem of deforestation, which needs careful consideration. However, cultivating plants that can grow quickly and using part of a tree for dye extraction without destroying the whole tree wherever possible could solve part of the problem.

So far many dye containing sources have been identified but they are simply not enough for large-scale dye production and to meet unlimited variation of color choices. Further research is required to identify new sources of dye extraction and their health and safety risks during dye production and use must be evaluated before the commercial application.

Most of the natural colorants come from plants, whose availability may depend on a particular season. This issue of seasonal availability can be addressed by converting the colorants into ready-to-use soluble powders or liquid concentrates with a long shelf life.

Again, the natural dye extraction process is complicated, time consuming, and not backed up by scientific studies. New scientific research in developing new technologies for dye extraction and application on textile materials is required to increase the productivity.

Commercial Challenge: Availability at a Comparable Price and Forms

Higher price of natural dye compared with synthetic dye is the key commercial challenge that the dye and textile industries need to address. Like any other mass-consumed products, the commercial success of the natural dye depends on cheap production at a very large scale. The current production techniques are not sustainable and must be upgraded to make them more efficient, faster, less resource intensive, and less waste generative.

The general practice in the textile industry is to produce colorants at a central facility and transport them to the dyeing facility for textile manufacturing through dyeing and printing. This centralized system presents a complex logistical challenge and can add significant production cost. Transportation cost can be reduced by a decentralized production system. The transportation cost is only a part of the total production cost. Therefore, every other cost associated with the whole production cycle such as raw material, labor, energy consumption, water consumption, etc. also needs to be significantly reduced to make natural dye a commercially viable option.

Similar to dye production, the textile dyeing process is also expensive owing to the requirement of skilled labor, and time-consuming and labor-intensive, complex dyeing process, where many industrial dyeing machines are not compatible with the natural dye.

The application of eco-friendly natural colorants in the textile industry is urgently needed in response to the growing consciousness of harmful environmental effects of synthetic dye on the earth. Environment conscious manufacturers of colorants and textile producers should come forward in investing heavily in research, development, and manufacturing of natural dyed textile. Furthermore, government regulations should be in place to discourage the use of synthetic dye. A global consensus between the world leaders should be made to reduce the consumption of synthetic dye as a part of the sustainable development summit. More importantly, consumer awareness initiatives on the health and environmental benefits of using natural dyed products should be undertaken via sustainability focused marketing campaigns. Results of a customer survey found that the majority (81.58%) of respondents will not buy natural dyed products due to relatively higher cost, poor color repeatability, difficult maintenance, and lack of color choices in the textile products (Kamboj and Mahajan, 2017). However, the consumer willingness to buy can be improved through increased awareness of benefits of natural dyed products. Most of the respondents strongly agreed to wear natural dyed products as it enhances their personality and brings them a “green,” conscious status. In addition, the new generation should be educated about sustainable development so that they can be informed decision makers, entrepreneurs, or consumers for maintaining future sustainability of the earth by promoting the use of natural dye.

Conclusion

Although natural colorants suffer from the limitations of higher price, low colorfastness properties, and low color reproducibility, avenues of improving them have already been identified through different research activities, as it has been mentioned in the previous sections. However, those innovations are yet to reach to the hands of commercial dyers and printers. Natural colorants are not abundantly available on the market in ready-to-use format although they are abundantly present in nature. Considering the environmental impact of producing and using synthetic colorants, natural colorants can be promoted as the safer alternatives capitalizing on their long history and heritage. Nevertheless, it should be emphasized that as it stands the natural colorants are only suitable for small-scale application and they can be only a complimentary option to synthetic dye rather than a replacement. In the long term, the natural colorants can be a competitor when they are produced at large scale in a cost effective way by solving technological, logistical, and commercial challenges through adoption of new technologies for dye extraction and dyeing, process

optimization and standardization, exploration of new natural sources, large scale cultivation of dye extracting plants, creation of a well-connected supply chain network, and improvement of consumer awareness.

Introduction

Electrochemical energy storage (EES) such as supercapacitor, batteries have become the key devices for electricity storing and transportation in recent years since they exhibit high performance, adaptability, and versatility. Recent developments in electronics and portable devices push the researchers and industries to develop more efficient EES devices with flexibility, high power and energy density, fast charge/discharge rate, and long life. Researchers are introducing new and advanced materials, and focusing on process engineering to put these building materials into devices to improve their performance. The performance of the EES devices fundamentally depends on the electrolyte ion and electron diffusion rate, high surface area, and architect of the engineered porous structure of the electrode materials. Supercapacitors and batteries are composed of electrodes, electrolyte, current collectors and separator in most of the cases. Common carbon-based conductive materials such as graphene, graphene oxide (GO), reduced graphene oxides (rGO) activated carbon (AC) are the widely used carbonaceous materials in EES devices due to some intrinsic properties such as high surface area, surface porosity, electron mobilization. Addition of some other polymers or metal oxides with common carbon-based materials significantly increases the device performance (Zhu *et al.*, 2011; Ervin *et al.*, 2014; Hyun *et al.*, 2017; Chua *et al.*, 2014; Borenstein *et al.*, 2017; Kim *et al.*, 2017; Khair *et al.*, 2019). Here in this article, we discuss the carbon-based conductive materials used in fabricating EES devices and their additive manufacturing 3D printing technology. 3D fabrication techniques in EES are significantly different from conventional fabrication methods. 3D printable colloidal ink require extra care to be produced and processed for fabrication. In industry, the conventional fabrication technique used for EES devices experience a few steps such as chemicals deposition, electrode rolling, roll cutting, cell assembly with a separator, electrolyte filling, and finally packaging with re-cutting. All of these steps are restricted in further scaling up fabrication methods other than making production line longer. On the other hand, 3D printing diminishes all of these steps. This novel technique allows fabrication of electrode, electrolyte separator chronologically using the command of computer aided software. Thus, this method is more scalable and sophisticated in energy storage device fabrication.

Supercapacitor and Active Material

Capacitance is the ability to store charge in the electrodes and the interface of electrode and electrolyte. Electrical double layer capacitor (EDLC) and pseudocapacitor are two supercapacitors that allow fastest charge discharge cycle as they avoid the kinetics of chemical reaction of batteries (Zhu *et al.*, 2011; Khair *et al.*, 2019; Jost *et al.*, 2014; Lu *et al.*, 2015). However, they suffer from low power and energy density.

$$C = \frac{A\epsilon}{4\pi d} \quad (1)$$

$$C_s = \frac{C}{m} \quad (2)$$

$$ESR = \frac{V_{iR}}{i} \quad (3)$$

$$E = \frac{CV^2}{2} = \frac{QV}{2} \quad (4)$$

$$P = \frac{V^2}{4R_s} \quad (5)$$

According to Eq. (1) accessible surface area A of electrodes and d path of ion diffusion are two critical parameters of these supercapacitors (Lu *et al.*, 2015, 2011; El-Kady *et al.*, 2016). Accessible surface area increases with the increment of pores, therefore capacitance depends on number of pores (Lu *et al.*, 2015). On the contrary, too high and too low pore size have negative impact on the capacitance (Lu *et al.*, 2015). The pore size must be equal to the size of ions of electrolyte. Because, larger the pore size higher the distance between pore wall and center of ion thus increasing the overall distance d which is inversely proportional to the capacitance (Lu *et al.*, 2015). This equation predicts that thickness of electrode is very critical parameter to obtain the highest capacitance. Researchers are printing electrodes with lower thickness so that ions can properly diffuse and current collector achieve high adhesion (Areir *et al.*, 2017b).

Specific capacitance is the intrinsic capacitance of electrodes which generates because of the material ability to hold charge, surface area and porosity, and it is calculated by dividing the capacitance (C) of electrode by its mass (m) or sometimes surface area Eq. (2). Specific capacitance does not determine the capacitance of the whole capacitor as it depends on other parameter such as electrolyte, ion diffusion

Fig. 1 Illustration of Electrical Double Layer Capacitor (EDLC) and Pseudocapacitor mechanism. (a) EDLC adsorb charge on its electrode surface and diffuse ion through the separator (b) Pseudocapacitor electrode surface facilitate fast surface redox reaction. path, ion accessibility and capacitor assembly (Lu *et al.*, 2015). Electrical sheet resistance (ESR) determines the internal resistance of capacitor which depends on resistivity of electrode and contact junction of electrode and electrolyte (Areir *et al.*, 2017b). Lower the resistance, higher the electron conductivity and higher the capacitance. Because of the high conductivity material such as graphene and Carbon nanotube (CNT) are popular choices for selecting the electrode material. ESR of an electrode is determined electrochemically in a capacitor in the presence of electrolyte from the voltage drop (v) and electrical current (i) at charge discharge cycle Eq. (3).

Energy density (E) and power density (P) are the outcomes of all architecture used in building the energy device. Some researchers also prefer to use current density to evaluate the efficiency of an energy device. Eqs. (4) and (5) determine that energy E and power P is directly proportional to voltage (v) of the overall capacitor, which critically depends on electrode material and electrolyte used in the capacitor. Ionic liquid, organic, and solid state- three types of electrolytes are being explored because of their unbalanced properties. Ionic electrolyte has higher concentration of ion and smaller ionic radii such as 1 M H_2SO_4 (Lu *et al.*, 2015). Smaller ionic radius facilitates ion diffusion through the pores of electrode and separator. However, they generate as low as 1.2 V in the electrode electrolyte interface of capacitor which reduce the energy density (Lu *et al.*, 2015). On the other hand, organic electrolyte such as polyaniline, acetonitrile, propylene carbonate generates 3–5 V in the capacitor. However, these organic electrolytes are sometime toxic and always requires as low as 3–5 ppm of water contents (Lu *et al.*, 2015). In order to implement the advantages of both electrolytes, scientists have been using a combination of organic and ionic electrolytes. 1 M H_2SO_4 and Polyvinyl alcohol (PVA) solid state gel electrolyte is the most common type of electrolyte being used commonly in supercapacitors (Zhu *et al.*, 2011; Khair *et al.*, 2019; Jost *et al.*, 2014; Lu *et al.*, 2015; Ambrosi and Pumera, 2016). This electrolyte gives the balanced electrochemical performance with sufficient mechanical stability by avoiding leakage problem of ionic electrolytes (Fu *et al.*, 2016).

In Electrical Double Layer Capacitor (EDLC) ions are adsorbed physiologically in the accessible surface of electrodes and in pseudocapacitor fast surface redox reactions takes place with the presence of additional capacitance material such MnO_2 and RuO_2 in the electrodes Fig. 1 (Zhu *et al.*, 2011; Ambrosi and Pumera, 2016; Zhang *et al.*, 2017). In theory, single layer graphene 2D sheet has the capacitance of $21 \mu F cm^{-2}$ and energy density of $169 Wh kg^{-1}$. However, practically graphene capacitors showed much lower energy density of $15\text{--}35 Wh kg^{-1}$ (El-Kady *et al.*, 2016). This discrepancy with the calculated energy density is attributed to the defective structure of graphene, its intrinsic nature of aggregation, intersheet junction contact resistance of printed electrodes (El-Kady *et al.*, 2016). Moreover, the pristine graphene has hardly any pores and limited accessible surface area. 3D printing technologies has recently been introduced in printing electrochemical energy storage devices in order to challenge these issue (Borenstein *et al.*, 2017; El-Kady *et al.*, 2016). Freestanding energy device such as hydrogel, aerogel, sponges, foams are the outcomes of 3D printing (Zhang *et al.*, 2017; Chi *et al.*, 2014; Foster *et al.*, 2017). Graphene-based electrodes are being printed in addition with bioplastics using direct 3D printing (Xu *et al.*, 2014). Electrochemical performance of energy device depends on the thickness of electrode to allow ion diffusion through them (Fu *et al.*, 2017). In comparison to 2D graphene 0D graphene nanosphere such as quantum dot avoids the restacking tendency with higher capacitance and faster response time because of their dimension (El-Kady *et al.*, 2016).

Nonporous Graphene

2D sheet of nanoporous graphene has superior electron mobility of $200,000 cm^2 V^{-1} s^{-1}$, high surface area of $2630 m^2 g^{-1}$, high intrinsic specific capacitance $550 F g^{-1}$, low thermal expansion with excellent thermal conductivity, flexibility, optical

transparency with exceptional mechanical strength (El-Kady *et al.*, 2016; Foster *et al.*, 2017; Yang *et al.*, 2015). High surface area and high conductivity make them suitable for energy devices, and its other properties such as flexibility and transparency replaced other traditional energy storing materials used in supercapacitors and batteries (Hyun *et al.*, 2017; Foster *et al.*, 2017).

Graphene Oxide

Graphene oxide, (GO) has been architected for direct 3D printing technology instead of pristine 2D graphene because of their ability to suspend and easy synthesis process (Le *et al.*, 2011; El-Kady *et al.*, 2016; Yang *et al.*, 2015). GO has attached functional groups such as OH⁻, COOH⁻, O⁻ etc. which provide electrostatic repulsion and the basal plane provide the Van der Waals attraction between the layers of GO (El-Kady *et al.*, 2016). Therefore, GO is suspended in common solvents very rapidly. On the other hand, 3D direct printable gel is prepared when the Van der Waals attraction outdo the electrostatic repulsion (El-Kady *et al.*, 2016). Preparation of GO suspension for electrochemical application requires some architecture and state of the art research. Traditionally, GO suspension is stabilized by using surfactant that is adsorbed in the surface of GO (Khair *et al.*, 2019). However, in order to fabricate electrochemical energy device GO ink must be prepared without the use of surfactant (Xu *et al.*, 2014) since surfactant adsorbed active material resists the penetration of electrolyte ion on its surface (see Fig. 2). Moreover, it increases the inter layer junction resistance and particle resistance which reduce conductivity (Ervin *et al.*, 2014; Le *et al.*, 2011). The GO suspensions of tuned rheology using additional polymer allow researcher to develop 3D printed architecture which is later reduced to evolve electrically conductive reduced graphene oxide (rGO). GO is a good electrical insulator; however, it is a very good proton conductor when moisture is adsorbed on the layers of GO sheet, Fig. 2 refer. This interesting property allows researcher to produce only rGO-GO-rGO supercapacitor without the presence of electrolyte and separator, where GO acts as an ion conductor (El-Kady *et al.*, 2016; Yang *et al.*, 2015). This capacitor has as high specific capacitance as 0.86 mF cm⁻².

Similar to aerogel, sponge etc., graphene 3D porous structure, GO is also 3D printed to produce aerogel (Zhu *et al.*, 2016) by treating the GO suspension with fumed silica powder to tune the ink rheology and produce porous graphene oxide (Fu *et al.*, 2017). Printed electrodes are also exfoliated to produce porous and rough surface in electrochemical device to increase ion adsorption on their surface. Researchers have explored many techniques to induce porosity in GO sheets such as annealing of KOH treated GO electrodes which induce nanoscale porosity, annealing of 1-butyle-3-methylimidazolium tetrafluoroborate treated GO control pore size of the GO sheets (Ervin *et al.*, 2014). Recently Das *et al.* (2016) have converted 2D rGO electrodes printed over cellulose paper into petal-like topological 3D rGO electrode using UV-laser pulsed light of wavelength 355 nm and energy 70 mJ cm⁻². 2D electrodes had 20 MΩ because of

presence of binder, unjointed graphene flakes, defected edge and residual oxygen group. Photon of laser light induces interconnected corrugated structure where graphene flakes are connected thus removing edge defect and creating continuous graphene sheet. Because the loosely packed carbon atoms of the flake expand horizontally which fills the inter flakes gaps by the energy induced by photon (Das *et al.*, 2016). Therefore, this connected graphene sheet has much lower resistance of $700\ \Omega$. Moreover, the stakes of graphene shrink laterally which induce the nano and micro scale petal like 3D structure which is responsible for high electrochemical performance of the energy device (Das *et al.*, 2016). Corrugated or wrinkled sheet of graphene where graphene flakes are jointed and for a 2D layer can also be obtained by high temperature thermal treatment of GO at 400°C because thermal treatment expands loosely packed carbon atoms of graphene flakes (Nathan-Walleiser *et al.*, 2014). Moreover, these high temperature thermal treatments decomposes the functional groups of GO which results in gaseous pressure in between the graphene flakes. As a result, GO of porous surface with surface area $593\ \text{m}^2\ \text{g}^{-1}$ is obtained which was later 3D printed to build electrodes of supercapacitor (Nathan-Walleiser *et al.*, 2014). A further improvement of this 3D fabrication method was conducted by bridging the rGO sheets using gold nanoparticles (Li *et al.*, 2016). In this process GO and HAuCl_4 ink was direct 3D laser written to fabricate micro electrodes of thickness $13.7\ \mu\text{m}$ and reduced to Au NPs an rGO by femtolaser beam irradiation of wavelength $1030\ \text{nm}$ and $80\ \text{mW}$ power (Li *et al.*, 2016). Gold nanoparticles largely improved conductivity of rGO because it acts as nanospace creator between the rGO sheets (Li *et al.*, 2016). Capacitance of this electrodes was also improved by photothermal evaporation of functional groups as gas from GO through superimposed 3D printed layers which leads to micro cavities in the electrodes (Li *et al.*, 2016). A supercapacitor was assembled using PVA/ H_2SO_4 gel electrolyte which showed 100 times much higher capacitance than that of bare rGO electrode supercapacitor even in lower scan rate. This high capacitance is clearly attributed to improved conductivity imparted by gold NPs which reduces ESR of the electrode (Li *et al.*, 2016) (Fig. 2).

Activated Carbon (AC)

AC is another porous structure of carbon which is built by chemical, thermal or combination activation of carbonaceous materials. KOH , H_2SO_4 , H_2O_2 , ZnCl_2 , H_3PO_4 are some common chemical treatment of activating carbon followed by high temperature ($\sim 1000^\circ\text{C}$) annealing using N_2 gas (Khair *et al.*, 2019; Islam *et al.*, 2019). Porosity and pore size largely depend on the rate of activation which creates pore in the surface of carbon. Generally, AC has been being used in 2D and 3D energy devices because of its surface area of $1700\text{--}1800\ \text{m}^2\ \text{g}^{-1}$ and moderate intrinsic specific capacitance of $92\ \text{F}\ \text{g}^{-1}$ (Areir *et al.*, 2017b; Brunet *et al.*, 2009). In 3D printed supercapacitor, AC is next to graphene and its oxide-based supercapacitor in terms of capacitance and energy density. In 2016 and 2017 Areir *et al.* (2017a,b) 3D printed AC slurry (AC and PVA) with a thickness of $2\ \text{mm}$ and $0.6\ \text{mm}$ respectively on a fabric surface to construct electrodes of supercapacitor. AC electrodes require additional current collector such as silver paint (Areir *et al.*, 2017b), gold, silver-zinc/polyvinylidene fluoride (Areir *et al.*, 2017a) because the electrode does not possess sufficient conductivity similar to graphene or carbon nanotubes. The two capacitor with different thickness used PVA/ H_2SO_4 (Areir *et al.*, 2017b) and PVA/ H_3PO_4 (Areir *et al.*, 2017a) solid state gel electrolyte in order to avoid leakage and mechanical distortion Fig. 3 (a-c). AC electrodes houses electro ionic charge in its high surface area which facilitates adsorption and diffusion of ions and electrodes during reduction and oxidation stages (Areir *et al.*, 2017b). The capacitors showed $68.7\ \text{mF}$ (Areir *et al.*, 2017b) and $1.4\ \text{F}$ (Areir *et al.*, 2017a) capacitance at $20\ \text{mV}\ \text{s}^{-1}$ scan rate. Such low capacitance (Areir *et al.*, 2017b) is attributed to the high thickness of electrode which hindered the current collector to channelized the electrons through the electrodes (Areir *et al.*, 2017b). Reduction of thickness lowered the kinetic movements of ion which finally resulted high capacitance (Areir *et al.*, 2017a).

Carbon Nanotube

CNT is a novel carbonaceous nano material which has superior conductivity, mechanical strength, aspect ratio, high surface area $1300\ \text{m}^2\ \text{g}^{-1}$, and resiliency. However, because of its extremely high cost of production and low accessible surface area CNT has not being used popularly on energy related application as electrode (Lota *et al.*, 2011). Moreover, pure CNT has capacitance as low as $5\text{--}40\ \text{F}\ \text{g}^{-1}$. Scientists have conducted many states of the art research to gain capacitance from CNT as it has very high conductivity. Interestingly, it has shown that, presence of nitrogen (N) as heteroatoms on outer wall of CNT provides high capacitance as N increase the electron wettability, and surface redox reaction (Lota *et al.*, 2011). Moreover, other pseudocapacitance material such MnO_2 , RuO_2 were also applied on CNT to obtain capacitance. Very recently, CNT based micro supercapacitor was 3D printed using a CNT ink which was prepared by ball milling process in the presence of a dispersion agent, ethylene glycol and isopropyl alcohol as solvent (Yu *et al.*, 2017). The 3D printed electrodes were assembled in the supercapacitor using PVA- H_3PO_4 solid state gel electrolyte Fig. 3 (d-h). Interestingly, post printing removal of dispersion agent improved the capacitance because of improved contact between CNT and electrolyte (Yu *et al.*, 2017). Both solvents add ink rheological property to facilitate 3D printing, where, isopropyl alcohol evaporates before the droplet touches the basal glass plate allowing partial solidification, and ethylene glycol evaporates post printing annealing (Yu *et al.*, 2017).

3D Printing Technology

Additive manufacturing also known as 3D printing has been widely used to rapid prototyping both in industry and academia over the last few years. It has emerged as a promising method for the fabrication of complex 3D structures by using advanced materials and

recently has shown the potentiality to replace the conventional techniques. 3D printing technology encompasses with a wide range of solid and ink-based methods, which make possible to fabricate 3D objects and patterns. This process starts with the creation of a 3D virtual model of an object using computer-aided design followed by layer by layer printing of the object. In EES device fabrication, the use of 3D printing has been increasing due to the control of electrode thickness, architecture, and geometrical shape. 3D printing technology exhibits the process flexibility, geometry controllability. 3D printed particle space architectures and pores enable the fast ion transport in EES devices which commensurate for fast charging/discharging. This technology ensures high active materials loading which promotes high energy storage. Precise layer by layer deposition of materials can control the thickness of the electrodes. High electrode thickness with uniform surface improves the energy density in unit area. Moreover, very low thickness electrode can also be fabricated for flexible EES devices. Wide range of materials such as polymers, composites, metal oxides, carbon-based materials, and ceramics can

also be printed by using various 3D printing processes for EES device fabrication. Here in this section, we will discuss about efficient printing methods of carbon-based conductive materials or composites.

Inkjet Printing (IJP)

3D IJP is an extrusion-based material conserving deposition technique that can print high-resolution 3D objects, patterns, and shapes of uniform thickness. The control of thickness, fineness and pattern geometry of the architect of carbon-based EES is well defined by this technology. The process involves the ejection of a fixed quantity of ink from a chamber, through a nozzle as a response of sudden, quasi-adiabatic reduction of the chamber volume via piezoelectric action. The chamber filled with liquid contracts in response to application of piezoelectric mechanical change under applied voltage. This sudden volume reduction sets up a shockwave in the liquid, which causes a liquid drop to eject from the nozzle (Singh *et al.*, 2010). The small ink droplet dries during the flight from the nozzle to the substrate because of their size. The droplets interact with the substrate and solidifies upon the subsequent annealing process (see Fig. 2a). Thus, high-resolution objects are created without spreading the ink droplets. Solidification of the ink and the pattern geometry of the EES depend on the volatility of the solvent and the ink rheological properties such as viscosity, viscoelastic behavior, and surface tension. The ink for IJP must be well formulated and free from agglomeration in order to avoid possible nozzle clogging during printing. IJP uses low viscous ink. The typical ink should be a dispersion or solution of active materials with a dynamic viscosity of less than 20 $\mu\text{Pa s}$ (de Gans *et al.*, 2004a) surface tension value below 80 $\mu\text{N m}^{-1}$ (de Gans *et al.*, 2004b). In general, the ink characteristics such as viscosity μ , surface tension σ , and density ρ , must be within certain ranges and satisfy certain rules for a fixed nozzle diameter d to allow the inkjet process to work properly. The inverse Ohnesorge number Z is commonly used to predict if a stable inkjet drop will be formed: $Z = \frac{1}{Oh} = \frac{\sqrt{\rho d \sigma}}{\mu}$, whereas ρ , d , σ , μ are denoted as ink density, nozzle diameter, ink surface tension, and viscosity, respectively. Only if $1 < Z < 10$, can the ink be expected to produce stable droplets (Zhang *et al.*, 2017).

Direct Ink Writing (DIW)

DIW is another extrusion-based material deposition technique that is typically carried out in room temperature. It's a versatile printing technique that can print carbon ink, hydrogel, melt polymer and ceramics for various purposes (Zhu *et al.*, 2017). The printing ink must have high yield stress and storing modulus to allow shape retention. DIW printing technique relies on the fluid flow-based printing of viscoelastic ink with shear thinning behavior. Fig. 4b shows that a pressure source (i.e., plunger) forces a liquid ink of active carbon-based materials with or without additives above the yield stress, allowing it to be selectively deposited through a nozzle. Once extruded, a sudden stress reduction, phase change, solvent evaporation, or combination of them restrains the deposited material into a specific shape. The solidification process competes with the gravitational fluid flow, 'wetting-out' and self-leveling tendencies of the ink and must be properly balanced to ensure shape retention and interlayer adherence (Wallin *et al.*, 2018). Post-extrusion heating can thermally evaporate the volatile solvent from the printed pattern and ensure porous structure electrode. Since DIW uses the high viscous liquid ink, the risk of nozzle clogging is very low. High mass loading of active materials in DIW printing technology ensures the significant amount of increase in the areal capacitance and energy density. Although DIW is the flexible printing technology, the resolution of the printed pattern and the pattern geometry largely depend on the diameter of the nozzle. DIW has been used for 3D printing of carbon-based materials such as graphene, GO, rGO, CNTs, and activated carbon for supercapacitor and battery (Borenstein *et al.*, 2017).

Fused Deposition Modeling (FDM)

In additive manufacturing, FDM is one of the popular and affordable 3D printing methods that create the 3D objects layer by layer by using melt cure polymers which are heated to melt the polymers at their glass transition state. In the FDM method, the preheated extrusion nozzle melts the filaments or wires and deposits the molten ink on a substrate. Later the molten materials are converted into solid state because of the cooling process. Biobased Poly (lactic acid) (PLA) and acrylonitrile-butadiene-styrene (ABS) are the widely used melt polymer in the FDM method (Zhang *et al.*, 2017). The resolution of the printed objects and pattern geometry are restricted by the diameter of the nozzle. In addition, the molten polymer can introduce heterogeneities, defects or voids. Melting temperature of polymer must be controlled to confirm that polymer filaments melt in the nozzle without creating voids. FDM method has been successfully used in 3D printing of carbon-based conductive materials for electrochemical energy storage devices (EES). Researchers have been using carbon-based materials as conductive fillers to fabricate conductive electrode. In order to use FDM printed 3D objects as an electrode for EES, conductive carbonaceous material such as graphene, GO, CNTs and AC must be incorporated in the molten ABS and PLA (Fu *et al.*, 2017; Podsiadly *et al.*, 2019). Fig. 5 shows the step by step process of producing GO-ABS composite for FDM in order to make a 3D printed electrode for EES applications. In this process, G/ABS composites, GO-NMP (5 mg/ml) and ABS-NMP (15 mg/ml) were homogenized (Wei *et al.*, 2015). The obtained composited was then extruded through a 1.75 mm diameter filament at 210°C. Then this filament was used in FDM to print 3D electrode. Graphene/PLA composite was also produced using the same way. Compared to other melt cure polymers, PLA is more environmentally friendly and biodegradable. CNTs and AC can also be promising candidate used as conductive fillers in the melt cure polymer composite for FDM. The incorporation of melt cure polymer improves the mechanical property in terms of bending and

stretching of FDM printed electrodes. However, the incorporation of melt cure polymer reduces the conductivity of the electrode. Nowadays, increase in the percentage of the conductive fillers and the removal of ABS and PLA via post-processing such as etching and calcination are carried out in order to solve this problem (Zhang *et al.*, 2017; Wallin *et al.*, 2018).

	Thermally reduced graphene oxide	Binder (>90% water, 8% glycerol and 2% other humectants)	SC	260 F g ⁻¹			(Azhari <i>et al.</i> , 2017)

Binder Jetting (BJ) 3D Printing

Binder jetting 3D printing is a powder bed additive manufacturing process which is inspired by the technology of inkjet printers. In this process, a liquid binder is selectively deposited on a powder bed with the print head. It's a growing process that allows the production of parts for the manufacturing medical and dental industries. This technique enables the production of metallic and ceramic parts as well as sand molds for casting (Azhari *et al.*, 2017). Nowadays this process is successfully used in EES device fabrication. To start this process, a 3D drawing is imported into the printer software (refer to Fig. 6). The powder to be used is placed in a dispenser which ensures a constant supply during printing. First, a powder layer of a specific thickness is poured thereafter the printing head moving on two axes projects binder where it is necessary. Before moving on to the next layer of the solvent contained in the binder is evaporated by an incandescent lamp. The powder bed is lowered and the new powder bed is deposited therefore the production takes place in a series of steps that build the part layer by layer. When the cycle is completed the binder is cured to remove from the printed objects by placing the container in a furnace. The temperature and time depend on the type of binder used in the printing process. After these steps, unbound particles are removed to reveal the part. According to materials used in this process, post-treatment is performed. In EES device fabrication, carbon-based conductive materials are used as the powder bed and then suitable binder for the materials are injected from the printer head (Zhang *et al.*, 2017). Recent literature reported on the fabrication of supercapacitor by using binder jet printing process. Thermally reduced GO particles were used as the powder bed, then the aqueous based binder was (>90% water, 8% glycerol and 2% another humectant) was injected through printing head. The printed electrodes were further impregnated with palladium nanoparticles in order to increase the specific capacitance and energy density (Azhari *et al.*, 2017). In this process, it is possible to build complex 3D structures with interconnected pores. Such interconnected pores resulting from the voids formed between powder agglomerates would also allow for rapid ion transport inside the electrodes of batteries and supercapacitors. The specific capacitance of printed graphene electrode is 265 F/g. This printing technique removes the process of formulating ink where no chemical solvents are used. Additionally, binder jetting printing reduces the microcracking from the supercapacitor electrodes because no subsequent evaporation of solvents requires like other 3D printing processes. However, this process is not still scalable for bulk manufacturing of EES devices and requires extensive study for all carbon-based materials (Ambrosi and Pumera, 2016).

Table 1 shows the compares the specific capacitance, energy density and power density of electrochemical energy storage devices varying different 3D printing processes, and selection of active materials.

Conclusion

3D printing technology has advantages over 2D printing methods because it eliminates different intermediate steps of fabricating energy devices by printing of electrode, electrolyte in a precise and predesigned fashion. 3D printing has made it possible to fabricate highly sophisticated micro structured energy devices for self-powered microelectronics. The thickness of electrodes can be critically controlled in the 3D printing process to optimize capacitance which is a key parameter of energy devices. In short, the ability to process renewable carbonaceous materials through 3D printing helps to create impact of functional materials for commercially viable energy storage applications.

Processing, Properties and Prospects of Nano-Biocomposites

Mohd H Othman, Tun Hussein Onn University of Malaysia, Johor, Malaysia

Introduction

In the field of polymer science, nano-biocomposites research had become recent interest and provide much opportunities, for both academician and manufacturing players. Since some of the pristine polymer's amount supplied from fossil fuel had decreased, efforts to reduce and replace the content of polymer in composites by using biomaterials have become the priority in research, development and commercialization. Nano-biocomposites have been manipulated in terms of mechanical, electrical, thermal and other properties to achieve possible encounters to understand, make prediction, and manage the potential application and prospect. Therefore, future industries could obtained the profits of these new material properties and in the same time reducing the impact towards the environment (Lau *et al.*, 2009).

Producing nano-biocomposites is heavily depending on the method of producing the nanocomposites itself, and the type/content of nanofillers. Before analyzing the nano-biocomposites, understanding their morphologies is essential, whereby different morphologies can be achieved for this advanced material. The early group of nanocomposites that was found were microcomposite (Alexandre and Dubois, 2000), intercalated nanocomposites (Ray and Okamoto, 2003) and exfoliated nanocomposites (Vaia and Giannelis, 1997a,b). The condition of microcomposite occurred when the aggregation of clay particles were achieved without the penetration of the polymer chains into the inter-layer spacing. As for the second group, the intercalated structures was obtained through the diffusion of the polymer chains in between the platelets. The third group is the exfoliated state, whereby delamination of clay layers were stacked individually, and dispersed homogeneously in the polymer matrix. The thing to be observed was the intermediate dispersion, where intercalated–exfoliated structures could happened. However, this division of groups was not consider the dispersion multi-scale structure, such as percolation phenomenon, preferential orientation of the clay layers, etc., (Ray and Okamoto, 2003). Thus, any discussion about how to prepare and defining the suitable method to process, as well as the gain properties and the potential prospect of nano-biocomposites material shall heavily reliant on these group.

Besides morphologies, the percentage of nanofillers content also plays important roles in improving the properties. Even small amounts of nano-sized fillers, with less than 10 wt%, could affect the outcomes. The outcomes could be in terms of extensive/strong interaction and well dispersed particles (Bordes *et al.*, 2009).

Nano-biocomposites research also depends heavily on the type of matrix used in the production of this material. Biopolymers matrix, or biodegradable polymers, produced through synthesized chemical or biosynthesized during the growth cycles of organisms. Table 1 proposes categories, example and family of bio polymers (Averous and Boquillon, 2004). According to categories, the last type of bio polymer which is synthesized from fossil resources was not obtained from resources which could be renewable (Bordes *et al.*, 2009).

Processing of Nano-Biocomposites

As stated in introduction, usual preparation of nano-biocomposites was subjected to the nanofillers condition bio-polymer's morphology. From this time, three major processing of nano bio-composites have been recognized. The processing techniques are (Ray and Okamoto, 2003):

- (1) In situ polymerization.
- (2) Solvent intercalation process.
- (3) Melt intercalation process.

In Situ Polymerization Process

Based on this approach, the monomer solution (liquid monomer) was utilized to swell the nano layer silicates. The existence of polymer formation will took place in between the intercalated sheets. Then, the initiation and propagation of monomer polymerization is materialized. During this process, the increment of macromolecules molecular weight and the condition of almost fully exfoliated morphology could be achieved for several studied systems. Some researchers have successfully perform this approach to produce nanocomposites (Messersmith and Giannelis, 1993; Alexandre and Dubois, 2000; Ray and Okamoto, 2003). According to some research, the polymerization process also can be commenced through (Ojijo and Ray, 2014):

- (1) Heat or radiation,
- (2) Diffusion of a suitable initiator.
- (3) An organic initiator.
- (4) Catalyst fixed through cationic exchange inside the interlayer before the swelling step by the monomer.

Table 1 Categories of bio polymers

No	Category	Examples	Family
1	Biomass polymers (agro polymers from agro resources)	Starch, lignin, xylan, chitosan, gluten cellulose	Agro polymer
2	Microbial polymers	Polyhydroxyalkanoates	Bio polyesters
3	Polymers of monomers, chemically synthesized (agro resources)	Poly (lactic acid)	Bio polyesters
4	Polymers of monomers, chemically synthesized (fossil resources)	Polycaprolactones, polyesteramides, polybutylene succinate/adipate	Bio polyesters

Source: Bordes, P., Pollet, E., Avérous, L., 2009. Nano-biocomposites: Biodegradable polyester/nanoclay systems. *Progress in Polymer Science* 34 (2), 125–155.

Most of the nano-biocomposites could be prepared through this approach, accept polysaccharides because the chains of this biomaterial were synthesized during the plant growth and then extracted from the vegetal (Chivrac *et al.*, 2009).

To quote more example, Hwang *et al.* (2009), have used this approach to prepare poly (butylene succinate)/montmorillonite nanocomposites through direct esterification and polycondensation. The objective of their research was to apprehend the function of urethane group, 1, 6-diisocyanatohexane, on the organoclay. The outcome of this research were the effects of preparation to the structure and properties of the poly (butylene succinate)/montmorillonite nanocomposites. They revealed that different extents of delaminated structures could be produced based on the modification of clay surface. This research was further expand to explore the effects of the same urethane modification on the poly (butylene succinate)/montmorillonite crystallization behavior, by applying the same nanocomposites preparation method (Hwang *et al.*, 2010).

Based on the review made by Ojijo and Ray, not many research that used this method have been published. Maybe the in situ polymerization process was quite intricate and costly. Henceforth, lots of research is focused on the beneficial of melt intercalation process (Ojijo and Ray, 2014).

Solvent Intercalation Process

As for the second method, this solvent intercalation process was expanded by utilizing the solvent system. The polymer used for this process was soluble with the swellable silicate layers. Firstly the polymer was dissolved in suitable solvent. The example of solvents that were used to swell the silicate layers are water, chloroform, or toluene. During the same time, to obtain a miscible solution, the swollen clay will dispersed into the same solvent. The weak forces that stack the layers together causing the layered silicates dispersed easily. As soon as the swelling is completed, the mixture of polymer solution with the layered silicate solution had been achieved. The polymer chains intercalation will occurred when both systems were pooled together. When the polymer chains intercalate, it will displaced the solvent within the interlayer of the silicate, and adsorb onto the silicate surface. The solvent evaporation process shall be the next sequence in order to get the final material in nanocomposites form. To quote one example, poly (butylene succinate)/clay or poly [(butylene succinate)-co-adipate] nanocomposites might be prepared by using this method. Once the solvent used in this method evaporates, the intercalated structure shall stay in the form of poly (butylene succinate)/clay nanocomposites or poly [(butylene succinate)-co-adipate]/clay nanocomposites (Ojijo and Ray, 2014).

According to the review made by Ojijo and Ray, more research was desired to be explored for this method. However there are few good references to be mentioned as the guidelines in processing, properties and prospects of nano-biocomposites intercalation (Ojijo and Ray, 2014). For instance, a research had reported about the preparation of poly (butylene succinate)/clay nanocomposites through solvent intercalation process (Shih *et al.*, 2007, 2008; Shih and Wu, 2009). However, based on the analysis of these researches, still there are lacking of details in procedures during solvent intercalation implementation. As for another example, a research had been performed about how to elucidate the solution intercalation procedure during the preparation of poly (butylene succinate)/clay nanocomposites. They used biodegradable aliphatic polyester (biodegradable aliphatic polyester)/montmorillonite nanocomposites, to characterize and perform analysis towards the material thermal and rheological properties. According to the results they managed to form a large intercalated structures of nanocomposites.

Nevertheless, they also found certain difficulties, whereby some of solvents are toxic (not environmentally friendly and only fewer attempts could be made). This method was less effective as compared to melt intercalation method (Lim *et al.*, 2002).

So it can be a caution to say that the drawbacks of this method are the consumption of abundant solvents, particularly for non-water-soluble polymers in solvent intercalation this process was not friendly to environment and causing cost expansion as well. Furthermore, lower interfacial interaction between the polymer and the clay surfaces could happened when there was still a slight amount of solvent remaining in the final outcome (Jin *et al.*, 2002). As for an example, for polysaccharides such as chitosan or pectin, due to high thermal or thermo-mechanical degradations, these biomaterials cannot be melt processed. Then, to yield polysaccharide/clay hybrid materials, massive used of solvent could took place (Chivrac *et al.*, 2009).

Melt Intercalation Process

The third method that can be used to prepare nano-biocomposites is melt intercalation. By using this method, the mixing of the polymer and the layered silicate was occurred during molten condition. The melt temperature during mixing was set above the

polymer's softening point. The thermodynamic interaction between the particles of host silicate and the polymer matrix will be the important key to achieve good formation of biopolymer nanoclay nano-biocomposites. This factor also shall influence the transportation of polymer chains, originally from the bulk melt into the silicate galleries. A sufficient compatibility between polymer and the surface of layer silicate will be the priority during this process. If this process is a success, then a range of nano-biocomposites with intercalated to exfoliate structure could be obtain. However degree of penetration of the polymer chains into the silicate galleries need to be monitored closely. As been mentioned before, this method was preferred not only due to no chemical solvent involved, but melt intercalation also near to extrusion and injection molding process. These processes are very well known as a massive industrial manufacturing method (Vaia *et al.*, 1996; Vaia and Giannelis, 1997a,b).

Based on the success of this method, most of the nano-biocomposites such as poly (butylene succinate)/clay nanocomposites or poly [(butylene succinate)-*co*-adipate]/clay have been prepared through this method (Ojijo and Ray, 2014). More details and advancement of research related to nano-biocomposites have been achieved through this method. To quote one example, besides the study of polymer/nanofiller affinity, the effects of the residence time and the shearing towards the nano-dispersion of the nanoclay have been studied. In order to induce the platelets delamination from the clay tactoids, shearing will be the key parameter that need to be control. As for the extended residence time, it will affect the polymer chains to diffuse into the inter-layer gallery. This diffusion is important to get an exfoliated morphology. The type of bio-materials used for this research comprehensively was polysaccharide. However, there are several drawbacks such as partial chains degradation could happened due to the thermal or thermo-mechanical inputs. Additionally, matrix degradation also becomes a problem due to long residence times, since a high residence times were needed to improve the clay exfoliation process. Thus, the balancing and optimizing parameter or processing condition during melt intercalation were necessary in order to reduce the degradation of chains and to get a fine exfoliated morphology (Chivrac *et al.*, 2009).

To quote another example of research related to melt intercalation process, the mixture of poly (butylene succinate)/C18-montmorillonites have been studied in term of preparation, structure, and mechanical properties. The first step in preparation was mixing the poly (butylene succinate) pellets and C18- montmorillonites organoclay in a bag. Then the mixture was melt extruding, with the temperature of 150°C to yield gray strands. After extrusion, the compound was pelletized and dried under vacuum for seven hour at 75°C. The drying process was perform because any moisture in the compound need to be eliminated. The pellets of poly (butylene succinate)/C18- montmorillonites nanocomposites were then transformed into sheets. These sheets were pressed in a mold at 1.5 MPa for three minutes at 135°C temperature to produce a sample with thickness range from 0.7 to 2mm. A rapid quenching process was performed towards these sheet, between glass plates. The next step was annealing for 1.5 h at 60°C temperature. The annealing process was performed to ensure the sheet was completely crystallize before measurement took place. In relation to the nanocomposites character/morphology analysis, it was found that the formation of stacked and intercalated layers of organoclay was successfully achieved (Ray *et al.*, 2002).

One more research that adopting the melt intercalation process involved with produce poly [(butylene succinate)-*co*-adipate]/C25A nanocomposites. Specifically in this research, the C25A nanoclay was twice-functionalised. The researchers used two types of silane coupling agents, which are (glycidyloxypropyl) trimethoxy silane and (methacryloyloxypropyl) trimethoxy silane. Firstly the organoclays need to be dispersed in methanol (10 g/ml) and sonicated for 10 min. The second step is to scatter the solution over the pellets of poly [(butylene succinate)-*co*-adipate]. Then this mixture was dried under vacuum. Melt intercalation process was performed for six minutes at 160°C temperature. Stacks of clay layers in the poly [(butylene succinate)-*co*-adipate] matrix was found well dispersed with multiple ordered platelets. There are several factors that could affect the degree of silicate layers exfoliation, which were the reaction between the end-groups of poly [(butylene succinate)-*co*-adipate] and the epoxy groups on the coupling agents, and the polar interaction between the ester groups in the coupling agents and poly [(butylene succinate)-*co*-adipate] (Chen and Yoon, 2005).

Properties of Nano-Biocomposites

In term of properties, the advancement of nano-biocomposites material with specific nano-structures have provide exceptional mechanical/thermal, conductivity and permeability properties. These materials have increasingly widespread and significant in terms of engineering applications through initiatives involving relevant research and development activities (Avérous, 2010).

Table 2 shows a summary of several nano-bio composite material properties obtained from previous research.

Application and Prospects of Nano-Biocomposites

There are specific reasons why researchers are fond of exploring more about nano-biocomposites. Obviously, the application of this new material could cater wide selection of engineering benefits towards many types of merchandises (prototypes or commercialized) by utilizing the special characteristic of this advanced composites. Besides, awareness and solutions have been taken towards the disadvantages of this material, especially any potential defects that could harm the users and environment (Avérous, 2010).

Challenges in understanding, predicting, and managing potential adverse effects should start from understanding the structure of nano-biocomposites, which compressed from biopolymer matrix with the additional of nanofillers that could improve

Table 2 Nano-biocomposites materials properties summary

No	Authors	Nano-biocomposites materials	Properties findings
1.	Fortunati <i>et al.</i> (2012)	Cellulose nanocrystals/poly(lactic acid)	● Good oxygen barrier properties ● Decreases of water permeability
2.	Oksman <i>et al.</i> (2006a,b)	Cellulose whiskers/poly(lactic acid)	● Good mechanical properties ● Increased of elongation to break
3.	Park <i>et al.</i> (2002)	Thermoplastic starch/clay	● Higher tensile strength ● Better barrier properties to water vapor
4.	Zaidi <i>et al.</i> (2010a,b)	Starch/clay	● Decrease of the weight-average molecular weight ● Faster thermal degradation of the poly (lactide) ● Slight increase of modulus and hardness
5.	Pirani <i>et al.</i> (2014)	Poly(lactic acid) and nanoclay (Cloisite 30B)	● Greater mechanical strength ● More ductile fractures
6.	Olivato <i>et al.</i> (2015)	Starch/poly (butylene adipate-co-terephthalate)	● Thermal degradation affected ● Increase in mechanical properties
7.	Corrêa <i>et al.</i> (2012)	Poly (hydroxybutyrate-co-hydroxyvalerate), montmorillonite clay and acetyl tributyl citrate	● Decrease in thermo-mechanical degradation ● Good mechanical and barrier properties ● Appropriated biodegradation kinetic ● Enhanced the crystallization ● Improving the thermal stability ● Increase the processing temperature range (lower melting temperature)
8.	Salaberria <i>et al.</i> (2014)	Starch, chitin nanocrystals and chitin nanofibers	● Better thermal stability, mechanical properties, and storage modulus
9.	Carli <i>et al.</i> (2011)	Cloisite® 30B,/halloysite, and poly(hydroxybutyrate-co-hydroxyvalerate)	● Increase in the Young's modulus
10.	Han <i>et al.</i> (2012)	Poly(lactic acid) with Graphite nanoplatelets (xGnP) and kenaf	● Enhanced the flexural modulus ● Positive effect on the heat distortion temperature
11.	Zaidi <i>et al.</i> (2010a,b)	Poly(lactide) layered silicate	● Increase mechanical properties, thermal and linear mechanical properties
12.	Furtos <i>et al.</i> (2016)	Nano forsterite biocomposites	● Good compressive, modulus and diametric tensile strength ● Improved flexural strength, modulus
13.	Chung <i>et al.</i> (2010)	Starch-clay	● Improved modulus and strength without a decrease in elongation at break

**Fig. 1** Potential application of nano-biocomposites.

properties with preservation of the material biodegradability, without eco-toxicity. Hence, the field that can utilize these benefits are bio medics and short period applications, such as hygiene devices, packaging, agriculture etc., (Bordes *et al.*, 2009). Some of the potential applications explored by researchers are displayed in Fig. 1 (Lau *et al.*, 2009; Salata, 2004).

Based on the trend of exploration with regard to nano-biocomposites application, more research have been steered either in in-vitro and in-vivo environments extensively. Research about the biocompatibility of natural polymer to assist bone repair, teeth filling, scaffolding, wound healing, artificial joint fabrication etc., have been carried out as the results of tissue engineering applications. Nano fillers such as nano-apatite, lamellar nanoclays (montmorillonites), and nanofibers (carbon nanotubes) have been utilized to improve the structure as the reinforcement. The addition of these materials could

Fig. 2 Critical success factors for nanotechnology. Reproduced from Sun, Y., Xia, Y., 2002. Shape-controlled synthesis of gold and silver nanoparticles. *Science* 298 (5601), 2176–2179

improve the mechanical and thermal stability (Avérous, 2010). To provide more examples about the applications and prospect of nano-biocomposites, several test had been conducted by previous researchers, in terms of drug delivery, organic dyes and controlling nano probes. More than that, further development had been steered to make these materials multi-functional and controllable by external signals or by local environment. Then, nano-biocomposites could be manufactured as nano-devices with wider engineering applications (Salata, 2004). In terms of bio-nanocomposites prospect as the packaging material, it is critical to justify the use of biomaterial in contact with food. Research needs to be done if the new food packaging product need to be produced from this material. Even though such advantages like better mechanical and barrier properties with the antioxidant and antimicrobial benefits, the potential hazards need to be monitored as well. The safety and risk associated with nanomaterials, migration properties, possible ingestion considering mechanisms for nanoparticles to interact with the human body and legal regulations need to be considered earlier before executing the applications (Jiménez and Ruseckaite, 2012).

Yet, until now, most nano-biocomposites are expensive, as compared to the conventional thermoplastic. Some of this material also too weak for practical use. Hence, the needs of improvement are vital to make them viable in the market. To extend their applications, more investigation about the formulation, optimization and blending of nano-sized fillers, could bring a more variety of improved properties such as stiffness, permeability, crystallinity and thermal stability (Bordes *et al.*, 2009). There are several issues related to bio-nanocomposites, such as nano reinforcement and polymer's compatibility and how much shear forces are needed to break the agglomerates apart. Certain areas need to be monitored such as isolation/separation of reinforcement material, degradation, suspension feeding problem, agglomeration of biopolymer, compatibility of matrix and biomaterial and extruder screw configuration (Oksman *et al.*, 2006a,b). Therefore, the success factors of these material's growth need to be summarized. There are five critical success factors for nanotechnology growth and development, as displayed in Fig. 2 (Sun and Xia, 2002).

In terms of the attraction and retention of industry partners, investors and corporate partners could be the success factor by commencing the effective sharing of context-rich technology knowledge. This action could increase the value for the nano-technology with minimal risk in achieving the necessary milestones in product development. As for product orientation, this factor should satisfy the focus on the single application, which is the most viable and attainable, and starting to make a list of prospects. Application of spiral product development methodology could engage the researcher with lead potential users. This engagement shall enhancing product development, by increasing the probability of product that could meet the customer's demand (Sun and Xia, 2002).

The next success factor is a continuous industry interaction and selection of a beachhead application. This factor could help the researchers in term of focusing on the development of the single most viable and attainable product opportunity once known, until it is successfully scaled-up or it fails. As for mitigation of nanotechnology, this factor provide the risk of the technology applied to this material, as the technical risk may occurred in the sense of costing, the control of quality and how much acceptance of this technology in manufacturing, as well as any treats towards the occupational and environmental health and safety considerations (Sun and Xia, 2002).

Conclusion

To conclude the findings of this article, the processing, properties and prospect of nano-biocomposites have been deliberated with appropriate explanations and examples. Usually there are four categories of nano-biocomposites, which were biomass polymers, microbial polymers, polymers of monomers chemically synthesized (agro resources) and polymers of monomers chemically synthesized (fossil resources).

Based on previous findings, montmorillonite were often selected for nanofillers. Hence, the processing methods were related to blend montmorillonite into the nano-biocomposites system. The methods are in situ polymerization, solvent intercalation process and melt intercalation process. Since the first and second method involves with the usage of chemical, which is not environmentally friendly, therefore, the third method which is melt intercalation was chosen. Moreover this method was eased for industrial mass production process. By using this method, the mixing of the polymer and the layered silicate was occurred during

molten condition, whereby the thermodynamic interaction between the particles of host silicate and the polymer matrix will be the important key to achieve good formation of biopolymer nanoclay nano-biocomposites.

In terms of properties of nano-biocomposites, a summary of material properties had been delivered, such as higher tensile strength, increment of storage modulus, improved barrier properties for gas /liquid, as well as faster degradation and thermal stability. To quote one example, a cellulose nanocrystals / poly(lactic acid) was found to possess good oxygen barrier properties and decreases of water permeability. Another example is a mixture of poly (hydroxybutyrate-co-hydroxyvalerate), montmorillonite clay and acetyl tributyl citrate. This blend could provide exceptional mechanical and barrier properties, decrease in thermo-mechanical degradation and provide appropriated biodegradation kinetic. This nano-biocomposite also could also enhanced the crystallization, improving the thermal stability and increase the processing temperature range with lower melting temperature.

Nano-biocomposites have many potential applications, such as tissue engineering growth, artificial joints and scaffolding from biocompatible polymers. This material also can be used as a primary and secondary airframe structures, jet engines and health monitoring, damage detection, and long-term degradation. However, to gain the benefit extensively, the critical factors to attain success in nano-biocomposites research need to be monitored, such as the attraction and retention of industry partners, product orientation, application of spiral product development methodology, continuous industry interaction and selection of a beach-head application and mitigation of nanotechnology. Yet, until now, most nano-biocomposites are expensive and too weak for practical use. Hereafter, more development and upgrading were needed to make nano-biocomposites viable in the market. To extend their applications, more investigation need to be executed, in terms of the formulation, optimization and blending of other types of nano-sized fillers. These recommendations were made to improve the properties such as stiffness, permeability, crystallinity and thermal stability of nano-biocomposites, so that these material have more demand in future.

Finally, this article could provide better understanding about nano-biocomposites, in terms of the processing, properties and applications of these materials. Since these materials are technically and financially competitive as compared with traditional composites, therefore it will open a new dimension of plastic manufacturing process, and in the same time encouraging more efforts in term of future research and applications, based on the established directions and recommendations summarized from this article.

Introduction

The palm oil industry in Malaysia and Indonesia are growing rapidly to become one of the key agro-industries of the world. The total production of crude palm oil in Malaysia was reported at 19,919,331 and 19,516,141 tons in the year 2017 and 2018 respectively (MPOB, 2016;2018b); which are about 21% of the Fresh Fruit Branch (FFB) of palm oil plant; and other 79% of FFB appeared as wastes. The estimated waste biomass materials are about 90 million tons, which regarded as palm oil mill waste and hazardous elements. These wastes are available in two forms as solid and effluent. However, it has been stated that palm oil mill waste is a bioenergy source (Shahidul *et al.*, 2018c). In the Malaysian case, over the last 30 years, the Malaysian palm oil industry has grown and at present, it is one of the largest agro-based industries (Wah *et al.*, 2002). The country's palm oil accounted for about 39% of the world palm oil production where the industry has contributed to the export earning of the country in the tune of about US\$3.2 billion. In the Indonesian perspective, this industry is stronger than Malaysia. It has been reported that in 2016 the total country's export was about 36.0 million tons which account for about 60% of the global palm oil production; and estimated waste biomass materials is about 170.0 million waste biomass materials (Khatiwada and Silveira, 2017).

The interest in renewable and clean energy sources is growing each day; due to the effect of fossil fuels on the environment relating to the reduction of global warming. Biomass-based energy would be an alternative to the conventional fossil fuels in providing cleaner and sustainable energy supply in the near future, as biomass is renewable. The current status of waste biomass material is the fourth largest energy source behind coal, oil and natural gas (Ladanai and Vinterbäck, 2009) by contributing about 9% of the total renewable energy sector. It is anticipated that the optimal use of biomass will contribute to reduce the formation of greenhouse gases and climate change effects. It is therefore argued that the optimization of the waste biomass used for energy production serves as a crucial means of mitigating the problem of fossil fuel scarcity while promoting sustainable development in the environment. However, the countries involved with Crude Palm Oil (CPO) production need technology and skills to convert hazardous palm oil mill wastes to produce energy for achieving sustainable energy supply. In this aspect, the waste biomass of palm oil mill would be providing us with three major benefits. Firstly, it will provide renewable energy supply which is known as Waste to Energy (WtE). Secondly, it saves the environment from the hazardous effect of wastes. And Finally, it reduces the working load on wastes materials management (Shahidul and Lamoh, 2017). In order to address these two issues, saving the environment and to produce renewable energy from waste biomass the current study has been carried out. Fig. 1 shows the stages of palm oil waste biomass production.

Fossil Fuel and Climate Change

The Fossil Fuel in Energy Landscape

Undoubtedly, fossil fuel resources, especially oil, coals, and gas will continue to dominate the global energy mix. Oil is the major hydrocarbon resource that poses an ultimate constraint to sustaining long-term economic growth and human progress. This is because there is no immediate viable substitute for oil as a dominant energy source in terms of its intrinsic qualities of extractability, transportability, versatility and cost (Singhania *et al.*, 2009). Close to 40% of the global energy consumption is based on

Fig. 1 Palm oil mill waste generation from the milling of palm oil fruit. Reproduced from Shahidul, M.I., Lamoh, M.M., 2017. Advanced Eco-Farming Technology to Achieve Sustainable Agriculture Growth in Sarawak, UNIMAS.

oil and no other fuel source holds as much energy as the oil is offering. Indeed, the petroleum oil holds 1.3–2.45 times more economic value per kilocalorie than coal (Hanson, 1999). Hence, it is an essential input in many of the production chains or economic activities but its long-run supply capacity is fixed and finite. Thus, continued exploitation of such limited resources would lead to depletion once it reaches its peak production level. EIA (2007) stated that the many of the global oil fields have reached their peak oil production levels and this scenario overserved in many counties include the Lower 48 States and East Texas oil fields in the United States, and the major North Sea oil fields in the United Kingdom and Norway (EIA, 2007; Euan, 2006; Kitani *et al.*, 2013; Zittel, 2001). Therefore, sourcing new sources of renewable energy and the use of it needs to continue as a substitute of depleting hydrocarbon based energy sources in order to reduce the greenhouse effect and to create sustainable energy supply (Shahidul *et al.*, 2018a).

Climate Change With the Fossil Fuel Energy Consumption

After hardworking of the last two decades to reduce fossil fuel consumption, there is no effective global deal to manage the risks of climate change. In this perspective, an obvious question to relevant stakeholders is, what is the next plan to achieve the goal of reducing climate change effect? Twenty years of hard work put into setup conferences, writing reports, intergovernmental meetings, placing public debate to reduce greenhouse gas (GHG) emission for mitigating climate change, but all efforts are nearly have failed. It seems essential to go back to the Paris climate change agreement for reviewing the status of carbon emission from the using of fossil fuel (Butler, 2019).

The reality is hydrocarbons continue to supply about 80% of global energy needs, just as they did two decades before. Indeed, the only difference is that the absolute amounts behind this percentage have grown. As a result, the amount of carbon emission continues to rise, and the estimated CO_{2eq} emissions become more than 40% higher than they were in 2000 (IPCC, 2017; Shahidul *et al.*, 2018a). The current global carbon emission situation is getting worse compare to the previous years. At this juncture, there is no viable collaborative mechanism active for tackling the global carbon emission problem. At this moment, the world is on an inexorable track to the point at which atmospheric carbon concentrations exceed the levels judged likely to raise temperatures by 1.5°C (IEA, 2015; International Energy Agency, 2017; Shahidul *et al.*, 2018a). As the climate change is connected to science, the answer to climate change problem should come first from science, and as well technology and engineering. To get the solution to this problem, the scientists should gather to get a solution rather than politicians who regularly meet to formulate solutions to the challenge (Shahidul, 2016). However, Lord Rees, former president of the UK's Royal Society, a scientific academy, has suggested for a few practical strategies to countering climate change in his most recent book entitled 'On the Future'.

They are improved electricity storage; increased low-carbon power generation; greater efficiency of consumption; and more reduction of emissions from methane, black carbon and CFCs all of which would contribute to mitigating global warming. However, the overall aim should be to identify, create and disseminate technologies that can give everyone the chance to use low-cost, low-carbon energy as soon as possible (Montford, 2012; Nurse, 2011).

The purpose of international events on energy and climate to mark progress on the ambitions expressed in the Paris agreement should be to confirm such choices, to share knowledge on the work being done in different parts of the world and to identify the areas where more effort and resources are needed. The exercise should not repeat the mistakes of the political debate over the past 20 years by always waiting for the slowest to catch up (IPCC, 2014; Sterner, 2015).

The other question relating to energy use and climate change is *how the science should be funded to address this issue*. The best answer is to pool available renewable resources for energy production. Why not the world communities establish an investment fund open to subscriptions from both the public and the private sector? Maybe the answer to this question is very difficult, because most world business giants are looking for profit. The technologies that meet the challenge of renewable energy from waste materials are likely to do well, and those who have invested deserve a reward. If some people generate income through the development of renewable products that serve the general public and community, good luck to them. The UN-backed conference

of the inter-government should start by accepting this reality that a part of their GDP may spend for research in developing renewable energy sources for mitigating the climate change. However, further work is needed to meet the goals of achieving a targeted carbon emission rate (Frankel, 2011; Nurse, 2011).

Palm Oil Mill Wastes Biomass

Palm Oil Mill Waste Biomass Materials in the Renewable Energy Landscape

Various studies on the energy potential of biomass waste offer a critical mitigating solution to fossil fuel resource constraints. The waste biomass materials also serve as an environmentally benign energy option to reduce waste disposal problems which at the same time reduces greenhouse gas emission. In the Southeast Asian perspective, the optimum use of the unutilized biomass materials would offer to reduce dependence on the fossil fuel-induced socio-economic development (Agamuthu, 2015). Particularly, optimizing the use of about 250 million tons of palm oil mill waste biomass would be a fossil fuel-saving approach (Shahidul and Lamoh, 2017); and at the same time, the use of waste materials would undoubtedly contribute to reducing the severe environmental problems (BE Sustainable, 2015).

The Economic development solely based on finite and depletable fossil fuel resources would bring serious effect on climate change; rather adopting the environmentally benign “waste to energy [WtE]” strategy would offer an inexorable solution to mitigate the entropic hydrocarbon resource depletion problem. Optimizing the use of biomass waste would also serve to protect the sink capacity of our biosphere from the cumulative environmental impacts of the ever-increasing volume of waste disposal (Shahidul *et al.*, 2018d). The Southeast Asian nations along with Thailand and other palm oil producer nations are shifting the geopolitics of global energy due to their insatiable appetite for energy demand amidst robust economic growth. However, the biomass waste materials would be a renewable energy resource as an alternative to the depletable fossil fuel reserves such as coal, oil and natural gas. Conceivably, the finitude fossil fuels coupled with increasing carbon footprint and anthropogenic climate change have led to growing regional interest in exploring alternative energy sources. One potential solution is to re-model the energy mix away from fossil fuel resources to waste biomass energy (Choy, 2016).

Palm Oil Mills Waste Biomass in Global Landscape

The palm oil industry in the global economic landscape is growing rapidly, and becoming one of the key agro industries of the world. In 2016, the estimated production of palm oil was about 58.000 tons with waste biomass about 170.0 million tons (Khatiwada and Silveira, 2017; MPOB, 2016). But, the waste biomass is negatively associated with the GWP and environmental hazard.

The palm oil mills generate a large number of organic waste materials, often these wastes mismanaged and dispose of the environment. These waste materials are two types such as solid and liquid. The liquid waste produces during the crude palm oil (CPO) process. The palm oil extraction process involves the use of water; it is estimated that for 1 ton of CPO produced, 5–7.5 tons of water is required, and more than 50% of the water will end up as palm oil mill effluent (POME) with biomass materials (Ahmad *et al.*, 2003). This waste biomass with POME is source of methane gas which is emitted to the atmosphere as greenhouse gas (Choi *et al.*, 2013; Shahidul *et al.*, 2018a). On the other hand, the optimal use of solid waste biomass is also expected to contribute to energy security, a significant reduction in greenhouse gas and mitigation of waste accumulation problems (McPhail *et al.*, 2012).

The palm oil mills generate a large quantity of organic wastes materials, and mostly in the Southeast emerging economies; these biomass waste materials remain basically unused or underutilized. This not only poses major disposal problems but also raises crucial environmental concerns. It is thus argued that optimizing the use of waste biomass materials for energy production serves as a crucial means of mitigating fossil fuel scarcity problem while also promoting environmentally sustainable development. This issue should be systematically analyses and demonstrated by scientist and policy maker for achieving sustainable energy supply to mitigate climate change effects (Shahidul and Lamoh, 2017; Kaewmai *et al.*, 2013).

Only in the Malaysian case, the palm oil plantation has expanded rapidly from about 54,790 hectares (ha) to about 1.26 million ha in 2014 and is expected to cover two million ha by 2020 (MPOB, 2014). The rapid expansion of the palm oil industry indicates the availability of waste materials, which would create an opportunity for producing renewable energy to reduce the dependence on fossil fuel for power generation. If the country comes forwards with funding for research to produce energy from waste materials of palm oil mill (MPOB, 2012; Rana *et al.*, 2017).

Carbon Emission From Palm Oil Waste Biomass Materials

Increasing palm oil demands in the global market is positively associated with global warming potential (GWP) due to its carbon emission intensity from waste biomass (Kaewmai *et al.*, 2013; Oosterveer, 2014). Indeed, biomass waste increases with the demand for palm oil. However, nowadays, this industry becomes a point of discussion of global carbon emission issue (Sridhar and Adeoluwa, 2009a,b). It was reported that CH₄, CO₂, and N₂O have a large share in the total global warming potential (GWP) (Wicke *et al.*, 2008). It has been also reported that the palm oil industry emits GHG in three ways (Shahidul *et al.*, 2018d). The first route of carbon emission is fuel burning in palm oil harvesting machinery. The second route is emission from electric production

Table 1 Solid and liquid waste produced per tonne of Fresh Fruit Bunch (FFB) processed

Biomass waste	Kg of waste from 1000 kg FFB
Empty Fruit Bunches	220
Palm Nut Shell	55
Mesocarp Fibre	130
Palm Oil Mill Effluent (POME)	650

to operate the process. And the third route is emission from the wastewater treatment process called POME (Zah *et al.*, 2007; Shahidul *et al.*, 2018d). Damen and Faaij (2006) and reported that the total GHG emissions from three routes are up to about 30 tCO₂eq (t CPO)⁻¹; and among this CH₄ emission is significantly harmful (Renewable Fuel Agency, 2008; Ng *et al.*, 2011). Reported that CH₄ emission potential of POME is about 9 kg (t FFB)⁻¹. The EIA (2007) stated that the total emission of POME would about 18.3 m³ CH₄ (t POME)⁻¹ including CO₂ and N₂O. Ng *et al.* (2011) reported that emission from FFB is about 190 kgCO₂-eq(tFFB)⁻¹. The Statistics Portal (2018) reported that CH₄ emission could be reduced from 9.0 m³ (t POME)⁻¹ to 5.5 m³ (t POME)⁻¹ by using efficient methane capturing technology (Chynoweth *et al.*, 2000). However, Sridhar and Adeoluwa (2009a,b), and Ng *et al.* (2011) reported that biogas (CH₄, CO₂, and H₂S) yield from POME would be up to 28 m³ (t POME)⁻¹. Based on the estimate made by Wicke *et al.* (2008) and Zah *et al.* (2007), the average emission from palm oil industries is about 30tCO₂eq (tCPO)⁻¹ and a similar report has been made by Damen and Faaij (2006). It was also reported that the contribution of palm industry to global emission was 1569.6tCO₂eq in 2013, 1680tCO₂eq in 2014, 1779tCO₂eq in 2015, 1824tCO₂eq in 2016 and 1854tCO₂eq in 2017 (Wicke *et al.*, 2008). This report concludes that palm oil mill waste materials is a potential source of methane gas emission and this gas should be captured and converted to energy to give a sustainable renewable energy supply (Shahidul *et al.*, 2018b).

Properties of Palm Oil Mill Wastes Biomass

It has been stated that palm oil biomass materials comprise (i) empty fruit bunches (EFB), (ii) palm kernel shells and (iii) mesocarp fibers, which are derived from the palm oil production process. The palm oil industry also generates substantial amounts of liquid waste in the form of palm oil mill effluent (POME) (Klimowicz, 2014).

In the aspect of waste biomass materials, a more serious observation is that only about a five percent of the total waste biomass potential is being collected and if all the usable biomass wastes are to be optimized for its energy potential, it would create 1.2 billion tons of coal equivalents (tce) or 0.84 billion tons of oil equivalent (toe) (Klimowicz, 2014). Other than Palm oil mill waste; Southeast Asia also has a huge biomass potential from various biological sources including 30 million cubic meters of woody biomass annually. This untapped biomass may be used for power and heat generation as a fossil fuel substitution. In this regards; Ohimain and Izah (2014) stated that the conversion process of FFB would produce 10%–30% CPO with the by-product of 30%–70% solid waste and 60%–70% palm oil mill effluents (POME). According to Nasution *et al.* (2014), the composition of solid wastes generated by the palm oil mills in Indonesia consists of fibers (12%–15%), shells (5%–7%) and empty fruit bunches (20%–23%), depending on the technology process applied; total accounts for about 165 million tons waste biomass materials. However, the palm oil mill waste in terms of unit weight of FFB and waste constituents are listed in Table 1.

Table 1 indicates that the waste biomass constitutes about 65% of total FFB. Considering 58,000 million tons of CPO production worldwide, the estimated waste biomass is about 275,000 million ton of waste biomass (Khatiwada and Silveira, 2017).

Renewable Energy Production From Palm Oil Mill Wastes and Environmental Sustainability

There are four types of waste biomass to energy conversion technology being used: a. *Thermal conversion*: Direct combustion, Pelletization, and Pyrolysis. b. *Thermochemical conversion*: Gasification, Liquefaction, and Torrefaction c. *Biochemical conversion*: Help of enzymes, bacteria and other organisms. d. *Chemical conversion*: Involves the use of chemical agents (Fauzianto, 2014).

By using all these technologies in waste biomass conversion, the societies would be benefited from harnessing renewable energy from palm oil mill wastes materials in two ways. Firstly, reducing the environmental burden due to reducing GHGs emission. Secondly, getting a sustainable energy source as a substitute for depleting and harmful fossil fuel (Shahidul *et al.*, 2018c; Kaewmai *et al.*, 2013). It has been also stated that the available palm oil mill waste would be used for bioenergy production, and this energy can be a crucial means of mitigating the pressure on hydrocarbon resource, reduce waste disposal management and the GHGs emission effect (Yoshizaki *et al.*, 2013; Yusoff, 2006).

The ensuing discussion highlights the fact that the search for alternative renewable energy sources in a finite natural world poses one of the biggest challenges humanity has ever faced. Biomass in general and palm oil biomass, in particular, can be a sustainable energy source to rely on. The palm oil waste biomass that available in the emerging Asian economies including Indonesia, Thailand and Malaysia would be a dependable renewable energy source (Kitani *et al.*, 2013).

Renewable Energy statement no 21 that made in 2013, stated that biomass accounted for about 19% of global final energy consumption, and biomass for energy (bioenergy) remained the major contributor to renewable energy worldwide at nine percent of all

Table 2 High heating value and proximate analysis of oil palm biomass residues in comparison with coal (mass fraction in % dry basis except for moisture content)

Sample	Gross calorific value (MJ kg ⁻¹)	Moisture content (wt%)	Ash content (wt%)	Volatile matter content (wt%)
Empty fruit bunch	18.88	67.00	4.60	87.04
Mesocarp fibre	19.06	37.09	6.10	84.91
Palm kernel shell	20.09	12.00	3.00	83.45
Oil palm fronds	15.72	70.60	3.37	85.10
Oil palm trunks	17.47	75.60	3.35	86.70
Bituminous coal	28.3	11.00	8.7	46
Lignite coal	2.8	39.00	10.7	29

Note: Choy, Y.K., 2016. Can palm oil waste be a solution to fossil fuel scarcity and environmental sustainability? A Malaysian case study provides the answer. *Waste Management and The Environment* VIII, 1, WIT Press, 97–108. doi:10.2495/wm160101.

renewables in the same year (REN21, 2015; Teske *et al.*, 2015). It was also stated that biomass is the fourth largest energy source after coal, oil and natural gas. It is also considered to be the most important renewable energy option (Ladanai and Vinterbäck, 2009).

Kramanandita *et al.* (2014) were working with palm oil mill solid and liquid wastes with the aim to evaluate its energy potential. The solid waste biomass in palm oil mill has divided into four components namely: waste biomass in fruit bunches is 53.63%, waste biomass in empty fruit bunches is 26.97%, Waste fiber 17.67%, and biomass in shells 6.46%. The composition of POME was mud (18.38%), biomass (30%) and water (42.05%). In this study, they concluded that the solid wastes are a potential source of biohydrogen, biogas, and bioethanol, while the liquid wastes (POME) is a source of biogas and biohydrogen.

It has been reported by Booneimsri *et al.* (2018) that bio-waste of palm oil mills (POMs) is an eco-friendly renewable energy source, which is economically and environmentally sustainable to produce steam and electricity, as what has been done in Thailand for decades. The author found the POMs is energy-efficient when used in the cogeneration power plant including recovery of waste heat emitted by sterilization steam venting and the biogas engine in the power generation system. The outputs of the palm oil mill biomass waste had been incorporated with the power plant, contributing to achieving sustainable electricity supply in Thailand.

It has been reported that Indonesia to be one of the major contributors of renewable energy sources in the world with its palm oil biomass potential (Fauzianto, 2014). The author reaffirmed his argument with research findings and other published data that palm mill waste contains 14%–15% fibre, 6%–7% palm kernel, 6%–7% shell, and 23% EFB which is biomass and a potential source of energy. However, the Government of Malaysia has set up renewable energy Policy and Action Plan to produce 2080 MW and 4000 MW electricity by 2020 and 2030 respectively; and the palm oil mill biomass waste will be used to achieve this target. In Peninsular Malaysia, the agricultural residue has been estimated at 17.0 Mt. out of which 77% of the total residues are from oil palm. Based on the energy potential of palm oil mill biomass waste that is listed in Table 2, the Malaysian government has been made target to produce renewable energy (Choy, 2016; Loh, 2017).

Table 2 demonstrates that the energy properties of palm oil mills biomass waste are higher than coals; in this aspect, palm oil mills biomass waste is a potential renewable energy source. It is glaring from Table 2 that optimizing the use of biomass from the palm oil industries has great potential to contribute towards greening energy-mix system, making it a sustainable substitute of fossil fuels towards increasing security in the power generation sector (Suruhanjaya Tenaga, 2014).

Energy Potentials of Palm Oil Mill Solid Waste Biomass

The Renewable Energy potential of palm oil mill solid biomass waste had evaluated by Harsono *et al.* (2012); in this study, the sample has been taken from for Malaysia and Indonesia. The estimated energy potential for each case is listed in Tables 3 and 4 respectively.

Table 3 demonstrates that waste biomass materials of Malaysian Palm oil mills are a good energy substitution of 323,731 tons of petroleum oil; which would contribute to reducing a significant amount of GHGs emission. Similar evaluations have made by Embrandiri *et al.* (2013) and Husain *et al.* (2003).

Table 4 demonstrates that waste biomass materials of Indonesian palm oil mills are a good energy substitution of 624,658 tons of petroleum oil; which would contribute to reducing a significant amount of GHGs emission. A similar study conducted by Embrandiri *et al.* (2013) and Husain *et al.* (2003). As demonstrated clearly in Tables 3 and 4, the total renewable energy potential of Palm oil mill waste biomass materials in Indonesia and Malaysia is about 10.0 billion kWh which may be a substitute of about 1.0 million tons petroleum oil; and this amount of energy recovery from palm oil waste could mitigate about 420 million tons of CO₂ equivalents (Langerak, 2018; Choy, 2016).

The Energy Potential at Solid and Liquid State of Palm Oil Mill Waste Materials

Choy (2016) has reported that the energy potential of palm oil mill waste materials in Malaysia and Indonesia are significant, and this amount of waste materials would be a suitable substitute for conventional fossil fuel. The estimated energy potential of these two countries is listed in Table 5.

Table 3 Energy potential of the palm oil industry in Sarawak, Malaysia (Malaysian case)

Methane emission (CO ₂ equivalent) (tonnes)	8,337,406	16,087,500	24,424,906	Mitigating greenhouse gas emission problem

Note: Choy, Y.K., 2016. Can palm oil waste be a solution to fossil fuel scarcity and environmental sustainability? A Malaysian case study provides the answer. *Waste Management and The Environment* VIII, 1, WIT Press, 97–108. doi:10.2495/wm160101.

As demonstrated in **Table 5**, the amount of renewable energy potential Indonesia and Malaysia in palm oil waste would contribute to mitigating greenhouse gas emission including CO₂ significantly; and as well as the substitution of fossil fuel (Embrandiri *et al.*, 2013; Husain *et al.*, 2003). It was reported that Malaysia and Indonesia may adopt zero-emission measures in the palm oil industries by optimizing the full use of available in palm oil waste materials (Shahidul and Lamoh, 2017) with the aim to achieve fossil fuel scarcity and environmental sustainability.

It is also demonstrated in **Table 5**, the amount of energy Indonesia may recover from palm oil waste is approximately 7.3 million kWh or 624,000 toe, and the amount of greenhouse gas aversion is about 643,000 tons of methane or 16 million tons of CO₂ equivalents. In the Malaysian case, it can be also seen from **Table 5** that the amount of energy may recover from palm oil waste is approximately 3.7 million kWh or 323,731 toe, and the amount of greenhouse gas aversion is about 333,496 tons of methane or 8.3 million tons of CO₂ equivalents (Choy, 2016).

In a study report, Kramanandita *et al.* (2014) stated that to meet the energy requirements of the palm oil mills, the solid wastes can be converted into biohydrogen, biogas, and bioethanol, while the liquid wastes can be converted into biogas and biohydrogen and water sources. The author further stated that the work station with the highest value of energy input and output is the sterilizer station by 385,008 MJ/h. The total energy produced by the by-product of palm oil mills was equal to 42,865 MJ/h consisting of the three largest components, namely condensate water (16,063 MJ/h), fibers (2722 MJ/h) and shells (8104 MJ/h). In this report, the author also added that to tap the energy potential of palm oil mills waste needs appropriate technology (Kramanandita *et al.*, 2014).

The potential of solid biomass wastes from palm oil mills as an energy source has been widely studied by Husain *et al.* (2003), Nasution *et al.* (2014) and Ohimain and Izah (2014). The energy potential of POME also studied by Gobi and Vadivelu (2013). The summary of all studies postulates that palm oil mills waste is a potential renewable energy source and an energy substitute for fossil fuel.

Renewable Energy Production From Palm Mill Effluent

This section of review demonstrates the research findings on methane potentials of POME. Historically, POME has always been regarded as highly polluting wastewater generated from palm oil mills (Begum *et al.*, 2013; Shahidul *et al.*, 2018d; Sterner, 2015) during CPO production (Ahmad *et al.*, 2003). POME is a brownish liquid composed of biomass, BOD and COD. POME is also recognized as a source of CO₂ and CH₄ emission responsible for GWP (Irvan *et al.*, 2012; Sarwani *et al.*, 2014). However, various research findings demonstrated that methane potential of POME could be a dependable renewable energy source instead of carbon emission (Chin *et al.*, 2013; MPOB, 2018a). It has been reported that about 28 m³ of biogas could be produced from 1.0 m³ of POME (Azri *et al.*, 2017), which has the methane potentials of about 15 m³. The POME is the most extreme wastewater compared to other wastewaters. The high organic value of POME can be converted into biogas production. Recently, the biogas system from POME has been utilized in several palm oil mills in Indonesia, Malaysia, and Thailand (Ichsan *et al.*, 2014).

The POME is also a potent source of methane emission when it undergoes an anaerobic process. By using methane capturing technology, this gas would be the most promising sources of renewable energy (Chin *et al.*, 2013). However, the composition of biogas produced from POME is listed in **Table 6**.

The biogas properties demonstrated that methane gas is the major component in biogas produced from POME (Rahayu *et al.*, 2015). The review of this section concludes that methane gas potential in POME is significantly high, which shall capture to achieve sustainability in energy supply.

Technology for Energy Production From Palm Oil Mill Waste

This section presents the review findings on the successful use of various technologies in biogas production from POME. A few anaerobic reactors have been listed in the scientific journals; though the operating variables and machinery are not much different from each other.

The COD balance and energy efficiency of the two-stage thermophilic reactor for biomethane production from POME were studied by Kongjan *et al.* (2013) with the aim to evaluate the energy yield. The estimated energy was 12.9 J/mL-H₂ (Kongjan *et al.*, 2011) for

Table 6 Composition of biogas

Element	Formula	Composition (Vol%)
Methane	CH ₄	50–75
Carbon dioxide	CO ₂	25–45
Water	H ₂ O	2–7
Oxygen	O ₂	<2
Nitrogen	N ₂	<2
Hydrogen sulphide	H ₂ S	<2
Ammonia	NH ₃	<1
Hydrogen	H ₂	<1

Note: Shahidul, M.I., Malcolm, M.L., Eugene, J.J., Mamunur, R., 2018b. Optimization of factors affecting biogas production from POME. Science International 30 (6), 851–859, (Retrieved from: <https://ir.unimas.my/22601/>).

hydrogen and 40.1 J/mLCH₄ for methane (Kongjan *et al.*, 2013). The energy yield of 0.95 kJ/g-COD was obtained from the hydrogen fermentation stage. The methane produced from POME by using the UASB reactor with an energy yield of 13.73 kJ/g-COD. The overall energy recovery from the was 14.68 kJ/g-COD. A similar result obtained from a laboratory scale two-stage anaerobic (Chu *et al.*, 2008; Mamimin *et al.*, 2015; Nathao *et al.*, 2013; O-Thong *et al.*, 2016). Khanal (2009) stated that the COD removal in the first stage was 15% and in the second stage was 73% and the total COD removal was 90% (Khanal, 2009). It was concluded that the two-stage anaerobic fermentation could increase COD degradation efficiency, increase net energy production with increasing of CH₄ production rates.

Methane Production From Combined Anaerobic Hybrid Reactor and Anaerobic Baffled Filter

Jeong *et al.* (2014) conducted an experiment with an Anaerobic Hybrid Reactor (AHR) and Anaerobic Baffled Filter (ABF) for methane production from POME. The specific objective of this study was to evaluate the effect of operating temperature on methane production. Both mesophilic and thermophilic temperatures were used in this study. The range of organic loading rate (OLR) to the combined reactors was from 2.0 to 15.0 kg COD m⁻³ d⁻¹ with Hydraulic retention time (HRT) of 5 days for AHR and 6 days for ABF. The methane production data demonstrated that the COD removal efficiency and methane production performance at thermophilic environment was about 93% at AHR and about 95% at ABF which is higher than that produced at mesophilic operations at about 35°C.

The research concluded that the combination of AHR and ABF in methane production from POME at thermophilic environment was higher than the mesophilic condition. The findings of this study also demonstrated that thermophilic environment at a temperature between 55 and 70°C would be the good option for producing methane by using combined AHR and ABF reactor (Jeong *et al.*, 2014; Shahidul *et al.*, 2018c).

Methane Production by Expanded Granular Sludge Bed Reactor From POME

By increasing COD removal performance from POME, methane gas production performance was tested by Wang *et al.* (2015) by using an Expanded Granular Sludge Bed Reactor (EGSB). The experiment was conducted at OLR 6.45 kg COD m⁻³ d⁻¹ and reactor were operated at 35°C temperature. In order to reduce a load of suspended solid from POME, a dissolved air flotation (DAF) equipment and Cationic polymer (PAM) was used. The VSS and effluent were circulated in the system to increase methane gas production performance of EGSB.

The experiment demonstrated that the COD removal efficiency was 94.89% with the biogas production about 27.65 m³ (m³ POME)⁻¹, which contains over 65% methane. The study concluded that the application of DAF and PAM in POME process for methane gas production was effective. It was also concluded that due to the reduction of suspended solids and recycling of the effluent, the organic materials conversion to methane had increased to a significant level (Wang *et al.*, 2015). A similar finding was reported by Shahidul *et al.* (2018c) while working on COD reduction from POME.

Methane Production From POME by Up-Flow Anaerobic Sludge Blanket-Expanded Granular Sludge Bed Reactors

Up-flow Anaerobic Sludge Blanket-Expanded Granular Sludge Bed Reactors (UASB-EGSB) used by Fang *et al.* (2011) with the target to improve biogas production performance from the bio-fluid POME. His interested was to evaluate the effect of palm oil free POME on biogas production. The UASB-EGSB reactor was operated with thermophilic conditions at 55°C with the adjusted pH 7.0. The reactor was operated at HRT of 10 days with the OLR range from 1.3 to 10.4 gVSS L⁻¹ d. Aged granulated POME sludge was used as the substrate to accelerate the digestion process.

The study demonstrated that the maximum methane yield achieved was about 503 mL-CH₄ gVSS⁻¹. When de-oiled POME was used in the same reactor, the maximum methane yield was 610 mL-CH₄ gVS⁻¹.

The study concluded that a combination of UASB-EGSB with de-oiled POME has higher methane potential, and thermophilic conditions have also contributed to increase biogas production performance.

Methane Production From POME by Anaerobic Sludge Blanket-Continuous Stirrer Tank Reactor

Krishnan *et al.* (2016) were working with POME for producing biogas as renewable energy. The research was evaluated the effects of various OLRs on H_2 and CH_4 production at the Anaerobic Sludge Blanket-Continuous Stirrer Tank Reactor (UASB-CSTR). The study was conducted in the two-stage digestion process. At the first stage, the UASB reactor was used to produce H_2 while the CSTR reactor was used in the second stage to produce CH_4 . Both cases, the study was conducted at the thermophilic conditions (55°C). The OLR was the manipulated variable, which varied at 25, 50, 75, 100, and $125 \text{ kg COD m}^{-3} \text{ d}^{-1}$ for UASB reactor. The OLR for CSTR were 4, 8, 12, 16, $20 \text{ kg COD m}^{-3} \text{ d}^{-1}$. The HRT was 6 days for both the digestion process. The CSTR was rotated at a constant 120 rpm. At UASB unit, the biogas production rate was 4.5 L d^{-1} with COD removal rate of 40% at OLR of $75 \text{ kg COD m}^{-3} \text{ d}^{-1}$. The performance of UASB started to reduce at OLR beyond $75 \text{ kg COD m}^{-3} \text{ d}^{-1}$. In the CSTR unit, the highest COD removal was 85% at OLR of 12 kg COD m^{-3} . The highest values for CH_4 content in biogas was 68%.

This research concluded that the two-stage digestion process contributed to an increase in methane gas yield. The microbial activities in hydrolysis and abiogenesis contributed to produce the substrate for the methanogens process, which enhance methane production (Krishnan *et al.*, 2016). A similar report has been produced by Shahidul *et al.* (2018a,b,c,d) when working on the optimization of COD reduction from POME.

Methane Production From POME by Two-Stage Thermophilic Fermentation and Mesophilic Methanogenic Process

Mamimin *et al.* (2015) studied with POME for evaluating the effects of two-stage thermophilic fermentation and mesophilic methanogenic process on digestion stability for methane production. At first stage he used Anaerobic Sludge Bed Reactor (ASBR) and operated at 55°C , the ASBR reactor was tested for hydrogen production at pH 5.5 and 2 days of HRT. Subsequently, the UASB reactor was tested for methane production at mesophilic temperatures between 28 and 34°C , at pH 7.5 and HRT of 20, 15, and 10 days.

While the ASBR was operated at OLR of $60 \text{ g COD L}^{-1} \text{ d}^{-1}$ and HRT of 2 days, the maximum hydrogen production rate was $1.84 \text{ L H}_2 \text{ L}^{-1} \text{ d}^{-1}$ with an average of $1.8 \text{ L H}_2 \text{ L}^{-1} \text{ d}^{-1}$. And at this operating condition, the COD removal rate was 38%. The maximum methane production rate was recorded of $2.6 \text{ L CH}_4 \text{ L}^{-1} \text{ d}^{-1}$ at HRT of 15 days and OLR of $6 \text{ g COD L}^{-1} \text{ d}^{-1}$.

In the UASB unit, maximum hydrogen production rate was $1.84 \text{ L H}_2 \text{ L}^{-1} \text{ d}^{-1}$ at the temperature of 55°C , HRT of 2 days and OLR of $60 \text{ gCOD L}^{-1} \text{ d}^{-1}$. The optimum HRT in the UASB was 15 days in which the maximum methane production rate was of $2.6 \text{ L CH}_4 \text{ L}^{-1} \text{ d}^{-1}$.

The study concluded that the two stages digestion process has contributed to increasing energy production yield from POME; though at UASB the HRT is higher compared to the CSTR system.

Engineering Efforts for Energy Production and Carbon Emission Reduction From Palm Oil Mill Waste

A few engineering activities are reported in published science journals for reducing CO_2 and CH_4 emission from palm oil mill waste (Ng *et al.*, 2011; The Statistics Portal, 2018). The total carbon emission was estimated from three levels: palm plantation; oil refinery at mills for CPO production and POME processing in open ponding system. The estimated carbon emission was $30\text{tCO}_2\text{eq}(\text{tCPO})^{-1}$ (Damen and Faaij, 2006), which was reduced to about 40% by the aid various engineering inputs (IPCC, 2007) such as installing carbon capturing machinery and advance technology in CPO production.

Yacob *et al.* (2006) and Sridhar and Adeoluwa (2009a,b) reported that the use of advanced technology in the palm oil industry for reducing energy consumption from $90 \text{ kWh}(\text{tCPO})^{-1}$ to $50 \text{ kWh}(\text{tCPO})^{-1}$ which contributed to reducing carbon emission. It was also reported that various engineering efforts have contributed to reducing GHGs emission to a significant level (Sridhar and Adeoluwa, 2009a,b; Ma *et al.*, 2010). Developing an anaerobic reactor for digestion of biomass-based palm mill waste to produce CH_4 is a significant contribution of engineering to the environment (IPCC, 2007; Kaewmai *et al.*, 2013). However, the most efficient anaerobic reactor development for harnessing energy from biomass waste materials was an important contribution which includes the expanded granular sludge bed (Oosterveer, 2014), up-flow anaerobic sludge-fixed film reactor (IPCC, 2007), and anaerobic fluidized bed single stage reactor (Zhang *et al.*, 2008).

The anaerobic reactor has been reported to be an efficient technology for biomass digestion to produce methane and to use in electricity production (Shahidul *et al.*, 2018d). Yacob *et al.* (2006) and Sridhar and Adeoluwa (2009a,b) reported that CH_4 emission reduced successfully from $9.0 \text{ m}^3\text{CH}_4(\text{tPOME})^{-1}$ to $5.5 \text{ m}^3\text{CH}_4(\text{tPOME})^{-1}$ by using efficient carbon capturing technology. However, Sridhar and Adeoluwa (2009a,b) and Ng *et al.* (2011) reported that CH_4 and CO_2 capturing capacity of an Anaerobic reactor is up to $28 \text{ m}^3 (\text{t POME})^{-1}$, which is high value-added innovation in engineering domain (IAI, 2016; Sridhar and Adeoluwa, 2009a,b).

Conclusion

Sustainable economic growth would be difficult to achieve with the use of current level backstop technology, lack of energy substitution, and continuing to exploration the finite fossil fuel. Given the finiteness of resources as well as the limited

capacity of our terrestrial biosphere to absorb GHGs, the current study demonstrates the harnessing the energy potential of the palm oil mill waste biomass which would enhance energy security and mitigating the climate change effects. With this view, the current review is conducted on palm oil waste biomasses with the aim to collect information on the energy potentials of this waste to support in mitigating the imminent threat of hydrocarbon resource depletion and renewable energy production (Choy, 2016; Shahidul *et al.*, 2018d). However, this review article aims to identify the various options of producing methane gas as renewable energy from palm oil mill waste biomass, and the various research findings have been formatted in line with WtE model (IAI, 2016; International Energy Agency, 2017).

Special emphasis has been given to collect information on methane production process and effectiveness of anaerobic reactors in optimizing CH₄ gas capture. The models used to estimate CH₄ potential in POME have been discussed in this article from the published scientific journals. This review also discussed the optimal operating condition of the anaerobic reactor for maximum biogas production. This study has revealed that global renewable energy potential as methane gas in POME is about 600 million m³ per year; which is mostly emitted to air as GHGs, having 25 times higher GWP potential compared to carbon dioxide (Abdullah and Sulaim, 2013; Shahidul *et al.*, 2018c). By using WtE model, this waste methane could be captured and used as renewable energy for producing heat and electricity (Langerak, 2018); and thus this paper could contribute to achieving sustainability in energy supply and environment.

Exploiting organic wastes as a source of renewable energy seems a promising alternative to energy sources; indeed, palm oil mill wastes in South-East Asia would be a good source for generating bioenergy due to its high organic contents (Choy, 2016; Shahidul and Lamoh, 2017). The abundant amount of palm oil mill waste biomass would provide the most reliable renewable and sustainable energy source if appropriate technology could be put in place. Thus, with the aid of technology and good governance, the palm oil industry would be able to contribute continuously to economic growth, and in supplying renewable energy (Aziz and Hanafiah, 2017).

However, this review could be a potential source of information for researchers involved in the field of renewable energy production from hazardous palm oil mill waste biomass including POME. This paper would be also a guideline in selecting a model to produce energy from palm oil mill wastes. Aside from this, the information published here would be utilized for renewable energy production to contribute to reducing about 37,251 million tons of CO₂-eq (Langerak, 2018) emission per year.

The summary of this study is about 270.0 million tons palm oil mill waste biomass available globally in a year would be an energy substitute of 189 million tons of coals which could reduce about 420.0 million tons carbon emission (Langerak, 2018; Choy, 2016). The study concluded that palm oil biomass waste materials are potential renewable energy sources for fossil fuel substitution to reduce climate change effects.

Wound Care: A Material Solution

Mohammad F Hossain, Bangladesh University of Textiles, Dhaka, Bangladesh

© 2020 Elsevier Inc. All rights reserved.

Introduction

Wound care materials are mainly fiber based products that include fibers, yarns, fabrics, and fibrous composites made from natural and synthetic sources. These fibrous substances have some outstanding characteristics in strength, elasticity, flexibility, length, fineness, cross-sectional shape and geometry, three-dimensional structures, air and moisture permeability, and liquid absorbency (Qin, 2016). Moreover, many fibrous substances have some unique inherent qualities such as biodegradability, biocompatibility, antimicrobial activity, hemostasis property, etc. Besides, the structural properties of fibrous materials and incorporation of functional additives provide additional functionalities of dressing products to treat specific wounds. Due to these structural and material characteristics they can show very effective performance in wound healing and management. Dressing materials act as a protective barrier permeable to moisture and oxygen, however, they can keep the wounds free from microbial infection and external contamination and shocks. Numerous dressing products, approximately 3000 types of wound dressings, in different forms are found in the current market used for caring for both acute and chronic wounds. According to their functions and uses most of the dressing materials are categorized as primary wound dressing or skin contact layer, absorbent pad, protective layer and bandage, etc. (Qin, 2016).

Wounds: Classification, Effects, and Healing Mechanisms

The term *wound* refers to an injury, damage, or break in the skin and surrounding tissues, or even any body part due to external actions such as physical, chemical, mechanical, thermal, or surgical actions. The Wound Healing Society states that a wound is the result of “disruption of normal anatomic structure and function” (Lazarus *et al.*, 1994). Damage or disorder of the skin by any means breaks the body’s protection system, and then pathogens can easily penetrate into the body to attack the normal biological systems, which primarily causes inflammation and infection locally or septicemia (septicemia is a systemic disease caused by pathogenic microorganisms, especially bacteria or their toxins in the blood. Usually it’s called “blood poisoning”) (Percival, 2002). This interrupts the physiological functions of injured body part. The disorder or injury of the skin or body part may happen due to disease, internal shocks, or penetration of any external objects into the body.

Classification of Wounds

Based on the nature and the duration of the healing process, wounds are classified into two major categories: Acute and chronic wounds (Boateng *et al.*, 2008). Usually, frictional contact, abrasions, or tears between skin and hard surface causes acute wound, for instance, tearing of the skin due to penetration of sharp objects (e.g., knives, bullet, surgical incision, etc.) into the body, burns, chemical injuries, etc. Sussman and Bates-Jensen (2007) define the acute wound as “a disruption in the integrity of the skin and underlying tissues that progress through the healing process in a timely and uncomplicated manner.” Although the healing time depends on the severity and nature of the wound, these types of mechanical injuries heal completely within a short time, usually 8–12 weeks (Percival, 2002; Boateng *et al.*, 2008).

However, the chronic wounds take longer time to heal, beyond 12 weeks, or even fail to do so because of repeated tissue insults or underlying physiological conditions such as diabetes, malignancies, persistent infections, poor primary treatment, and other patient related factors, for example, food habits and lifestyle, etc. (Moore *et al.*, 2006; Boateng *et al.*, 2008). Chronic wounds cannot proceed through the normal healing process in an orderly and timely manner, or even fail to restore normal anatomic and functional integrity (Lazarus *et al.* 1994). Sussman and Bates-Jensen (2007) define a chronic wound as “one that deviates from expected sequence of repair in terms of time, appearance, and response to aggressive and appropriate treatment.”

The chronic wounds fail to progress through the healing process according to the expected pattern and they do not provide restoration of structural or functional integrity of the wound tissues (Ovington, 2007). Examples of chronic wounds include decubitus ulcers such as bedsores or pressure sores and leg ulcers such as venous, ischemic, or of traumatic origin (Boateng *et al.*, 2008). In general, chronic wounds include pressure ulcers, diabetic ulcers, venous leg ulcers, vascular ulcers, arterial ulcers, pressure ulcers, etc.

Wounds can also be classified as superficial, partial-thickness, and full-thickness wounds. Superficial wounds affect only the surface of the epidermis layer of the skin, whereas the partial-thickness wounds affect both the epidermis and dermis layer, and full-thickness wounds affect epidermis, dermis, and the deep of subcutaneous layer (Boateng *et al.*, 2008).

Complications of Wounds

Infection

Microbial acquisition by wounds includes three distinct phases: Contamination, colonization, and infection (Copper, 2005). At the initial stage of injury microorganism contamination may occur but these microorganisms cannot multiply or persist due to the

action of inflammation of the wound. Inflammation is responsible for removing the microorganism contamination. However, when the decontamination process does not work properly and contamination exists in the wound, a prolonged inflammation occurs that ultimately leads to colonization and invasive infection (Guo and DiPietro, 2010). This happens when the self-resistance of the body's immune system fails against microorganisms. As a result, localized wound infection occurs and uncontrolled colonization of microorganisms exists in the wound (Baranoski and Ayello, 2012).

The term "contamination" refers to the presence of nonreplicating microorganisms in a wound, while the term "colonization" represents the presence of replicating microorganisms in the wound without tissue damage (Guo and DiPietro, 2010). When a microorganism colonization exists in the wound, the normal healing process is hindered seriously and the wound becomes infectious or complex, which is seen in most chronic wounds. Hence, the wound infection can be defined as "the invasion and multiplication of microorganisms in wound tissue resulting in pathophysiologic effects or tissue injury" (Altemeier, 1976). In the infection stage, the microorganisms grow, divide freely, and cause invasion into host tissues that leads to cellular injury and explicit host immunological reactions (Copper, 2005). The wound infection causes serious problems that can lead to delays in recovery as well as adverse patient complications such as sepsis, amputation, and even death (Harding and Renyi, 2009). Experts (Dowsett and Newton, 2005; Cutting and White, 2004a; Stotts and Hunt, 1997; Collier, 2004) have identified the following common signs and symptoms of infection that are observed in both acute and chronic wounds:

- Pain
- Erythema (redness of the skin)
- Edema (swelling or fluid retention in the skin)
- Purulent discharge and (drainage of pus)
- Higher body temperature

However, chronic wounds include the following additional signs along with the above symptoms:

- Delayed healing
- Increased exudates
- Bright red discoloration of granulation tissues
- Generating friable tissues
- Spread of the infection into surrounded area
- Malodour

Exudates

Although the discharge of exudates is a part of the normal healing process it may be a sign of an infectious or chronic wound. In this case the volume of exudates increases rapidly, and the exudates become viscous and malodorous. If the overflowed exudates are not managed properly they may spread over the surrounding area of the wound and may attack the fresh tissues to cause maceration (the softening and weakening condition of skin due to prolonged contact of liquid or exudates, which may cause the breaking down of the skin) (Bishop *et al.*, 2003). Due to maceration the surrounded tissues become fragile and unfasten, which may lead to breakdown of the tissues from a minor shock (Fletcher, 2002). This situation deteriorates the clinical status of the wound and seriously affects the patient's well-being. Moreover, the exudates may bring on allergic irritation and discomfort in the surrounding skin.

Necrotic tissues

Sometimes the wounded tissues may die due to insufficient supply of blood and nutrients, which lead to dehydration of the tissues. These tissues then form a black leathery bead or layer on the surface of the wound. When the bead becomes dry it shrinks and causes localized pain and discomfort. Moreover, the necrotic tissues are also responsible for causing a bad smell.

Malodor

Wound malodor is a side effect of infectious and sloughy wounds. The malodorous wounds create enormous psychological pressure on the patient and the quality of life of the patient is seriously affected. Several factors are associated with this situation: Bacterial infection, tissue necrosis, and exudates. In general, the infectious chronic wounds such as ulcers, fungating lesions, and malignant wounds produce an extreme foul odor.

Wound Exudates

The fluids produced as the result of vasodilation (widening of blood vessels) during the early inflammatory stage of healing and discharged from a wound are called exudates. Due to the disruption of dermis a variation of tissue fluid pressure occurs between the unwounded (high fluid pressure) and wounded (low fluid pressure) area, which leads to the spillout of fluid from the wound (Vowden and Vowden, 2004). This fluid is generated due to the influence of inflammatory mediators such as histamine and bradykinin. Microbial colonization of wounds, especially in the chronic wounds, causes vasopermeability that increases the loss of wound fluid (Hampton, 2004). Exudates are a part of normal healing process and maintain the "moist-wound" environment, which ultimately helps the healing process (Thompson and Stephen-Haynes, 2007; Winter, 1962). Moreover, the wound fluid supplies essential nutrients and growth factors to the wound, which assist the reformation of the epithelium. However, excessive

fluid secretion from the wound causes maceration (softening) and other complications in the surrounded area. Exudates are composed of different molecules and cells like white blood cells, red blood cells, platelets, enzymes, glucose, fibrin, plasma proteins, growth and immune factors, microorganisms, electrolytes and inflammatory mediators, etc. (Adderley, 2010; White and Cutting, 2006).

The acute wound exudates contain high protein contents, molecules, and cells that assist the healing process whilst the chronic wound exudates contains proteolytic enzymes that degrade the growth factors, which ultimately hampers the healing process (White and Cutting, 2006). Chronic wounds contain more dead white cells, bacteria, high levels of inflammatory mediators, and protein digesting enzymes that disrupt the healing process and create an irritating environment in the surrounding area of the wound (Adderley, 2010). The exudates of chronic wounds can slow down or even hinder the migration and proliferation of the cells, which ultimately affects the wound healing and repair (Schultz *et al.*, 2003). Overall, the excessive discharge of wound exudates may cause several problems such as maceration or propagation of wound to the surrounded skin, pain, malodor, protein and electrolyte loss, dehydration, delayed healing, sustained infection, soiled clothing and bedding, etc.

Wound Malodor

Unpleasant odor from a wound causes tremendous distress and embarrassment for both the patient and the carers. The quality of life of a patient with a malodorous malignant wound is seriously affected due to the physical obstruction and mental pressure. A patient with malodorous wounds suffers from some physical and psychological disorders, which include pain, bleeding or exuding, itching, alteration of body image, depression, denial, shame, guilt, fear, disgust, lack of self-respect and confidence, problems with sexual expression, and social isolation (Naylor, 2002). Most of the infectious chronic wounds such as venous leg ulcers, diabetic foot ulcers, pressure ulcers, and fungating lesions or malignant wounds are responsible for producing bad smells (Thomas *et al.*, 1998).

Exudates do not create any unpleasant odor at the initial stage of a wound but they may spread a bad smell when the wound becomes sour and increased bacterial growth or infection occurs. Due to the loss of vascularity in the malignant wounds aerobic and anaerobic bacteria proliferate rapidly and cause malodor with abundant exudates (Morris, 2008). At this stage the malodor is generated due to bacterial decomposition of serum proteins present in the wound fluids (Lipman and van Bavel, 2007). The mixture of volatile agents, which include short chain organic acids such as n-butyric, n-valeric, n-caproic, n-haptanoic, and n-caprylic acid, that are produced by the action of anaerobic bacteria, together with a mixture of amines and diamines such as cadaverine and putrescine created by the metabolic processes of other proteolytic bacteria produces the bad smell (Moss *et al.*, 1980; Thomas *et al.*, 1998). Anaerobic bacteria such as *Bacteroides* and *Clostridium* and aerobic bacteria such as *Staphylococcus aureus* and *Pseudomonas aeruginosa* are mainly responsible for producing offensive wound odors (Fletcher, 2008). Moreover, the necrotic or sloughy tissues of the wounds with excessive exudates also produce wound malodor (Lee *et al.*, 2006).

Wound Healing Mechanism

Wound healing is a complex biological process, which is largely related to physiological parameters of growth and regeneration of damaged cells. It can be defined as the physiological processes by which the body replaces and restores the functions to damaged tissues (Lee *et al.*, 2006). The body regenerates the dermal and epidermal tissues through a natural healing process. The natural healing process begins when the wound occurs and ends with complete wound closure. There are some distinct but overlapping biological and physiological phases of the wound healing process, which include hemostasis, inflammation, migration, proliferation/repair (regeneration of cell), and remodeling (maturation) (Zahedi *et al.*, 2010).

Hemostasis refers to stoppage of bleeding, which is considered as the first stage of the wound healing process. In the inflammatory phase, the neutrophils (first type of white blood cell) and the monocytes (second type of white blood cell) enter into the wound and begin the critical task of phagocytosis to remove unwanted or foreign materials, microorganisms, and damaged tissues from the wound (Diegelmann and Evans, 2004). During the migration phase the epidermal cells and fibroblasts are relocated into the wound and replace the injured and damaged cells (Boateng *et al.*, 2008). In many references this phase is merged with the proliferation phase and it was not shown as a separate phase. The proliferation phase begins with growing and depositing extracellular matrix (ECM) in the wound. At this stage, the wound is fully covered with epithelium and new granulation tissues are formed in the wound (Zahedi *et al.*, 2010; Baranoski and Ayello, 2012). At the end of this stage the epidermal cells reach to the normal level of the skin that restores the skin structure. Thus, this phase is considered as the repair stage of wound. The regenerated ECM becomes cross-linked and organized during the final remodeling phase (Diegelmann and Evans, 2004). At this stage the wound is completely recovered and refilled with new cells, and no surface flaws are left in the skin.

Wound Treatment and Management

Treatment and management of wounds are extremely difficult when they become complex with sustained infections. A number of potential factors such as the size, shape, depth and position of the wound, the status of infection, the status of exudates, the presence of necrotic tissues, and the presence of malodor need to be considered for choosing the treatment and the management

technique of wounds. Krasner (1995) identified some key tasks that can manage the chronic wounds effectively: Preventing wound infection, optimizing exudates control, removing foreign bodies, and preventing premature wound closure or contracture, especially in the case of infected or undermining wounds. In general, wounds, whether acute or chronic, partial or full-thickness, need either medication or dressing, or both. This section focuses on the formats of different dressings and their functions, advantages, and disadvantages.

Medication for Wound Treatment

Although acute wounds may heal without any medication, infectious wounds need medications, mainly antimicrobial therapy. Antimicrobial therapy comprises antiseptics and antibiotics, which act directly to eradicate microorganisms involved in the infections. Antibiotics such as gentamicin, ofloxacin, minocycline, tetracycline, and metronidazole are used as selective agents and administered systematically to kill microorganisms. However, antiseptics are normally used as nonselective cleaning agents, which reduce the microbial growth in the wound. Antiseptics containing silver and iodine are also effective for killing microorganisms. The most common antiseptics that are used in wound treatment include acetic acid, chlorhexidine, silver, iodine, honey, hydrogen peroxide, sodium hypochlorite, potassium permanganate, polyhexamethylbiguanide, triclosan, etc. (Qin, 2009). These antimicrobials can be applied to the wounds in the form of liquid, lotion, ointment, soaked with dressing, or incorporated with the dressing materials to achieve the optimum results. However, antiseptics have toxic effects on human cells and the emergence of bacterial resistance to antibiotics are the two potential drawbacks of using these agents in wound treatment.

Furthermore, several growth factors such as epithelial growth factor (EGF), platelet derived growth factor, fibroblast growth factor (FGF), transforming growth factor (TGF), insulin-like growth factor, and human growth hormone are used to facilitate wound healing (Steenfos, 1994). Besides, vitamins A, C, E and the minerals copper and zinc can also be used to promote wound healing (Wallace, 1993).

Silver as Antimicrobial for Wound Treatment

Silver has a long history in the treatment of burns and chronic wounds even in cases of venereal diseases, fistula from salivary glands, bone, perianal abscesses, postoperative cares, and in different medical devices to sterilize them (Lansdown, 2002). In the health care sector, the bioactive silver ion (Ag^+) has widely been used in wound dressings, catheters, bone cements, dental devices, hygiene textiles, and other associated products to achieve antibacterial or antifungal properties (Lansdown, 2002). Also the other forms of silver such as silver nitrate, silver sulfadiazine, silver oxide, silver phosphate, silver chloride, silver zirconium, organic complexes of silver, and silver nanoparticles can be used as antimicrobial agents (Qin, 2009; Lok et al., 2006).

Although silver has some toxicity to mammalian cells, clinicians still prefer using silver to treat and manage infectious wounds because of the emergence of antibiotic-resistant bacteria and potential side effects of using antibiotics (Chopra, 2007; Parsons et al., 2005). Silver is an effective antimicrobial against a large number of microbes with minimal toxicity to mammals at low concentrations (Jones et al., 2004; Lansdown, 2002). It is an effective killing agent against a broad spectrum of bacteria: Gram-negative such as *acinetobacter*, *escherichia*, *pseudomonas*, *salmonella*, and *vibrio*, etc. and Gram-positive bacteria such as *bacillus*, *clostridium*, *enterococcus*, *listeria*, *staphylococcus*, and *streptococcus*, etc. (Burrell et al., 1999). Silver is also effective against antibiotic-resistant strains such as methicillin-resistant and vancomycin-resistant *S. aureus* and *Enterococcus faecium* (Percival et al., 2007).

Chemically, metallic silver is an inert substance but when it comes in contact with moisture of skin or wound fluids it produces active silver ion (Ag^+), which acts as a biocidal agent. The Ag^+ is the functional site of a silver compound, which can react with negatively charged components of proteins and nucleic acids of bacteria, thereby causing structural deformation and reformation in the bacterial cell wall and membrane. The Ag^+ then enters into the cell to damage the DNA and bacterial proteins involved in key metabolic processes of bacteria, impeding bacterial replication and, ultimately, leading to cell death (Dallas et al., 2011; Chaloupka et al., 2010). Ag^+ has a high affinity towards sulfur and phosphorous containing cell membrane and reacts with sulfur containing proteins inside or outside the cell membrane, which destroys the cell viability of the bacteria (Morones et al., 2005). It is believed that ionic silver strongly interacts with phosphorous moieties in DNA that results in the inactivation of DNA replication (Matsumura et al., 2003).

Silver not only shows antimicrobial activity but also stimulates the epithelialization of a wound by increasing the concentration of calcium ions in the wound surface. In the last century, silver nitrate was used to remove granulation tissues to promote epithelialization and promote skin formation on the surface of wounds (Rai et al., 2009). Moyer et al. (1965) reported that silver nitrate of 0.5% solution possesses effective antibacterial property against *S. aureus*, *P. aeruginosa*, and *Escherichia coli* without affecting the epidermal proliferation. Moreover, silver decreases surface inflammation, surface metalloprotease activity, and exudates matrix metalloprotease activity for assisting wound healing (Lakshman et al., 2010).

Wound Dressings

Wound dressings are the materials that can produce a physical barrier against microorganisms and soiling but allow moisture and oxygen. These materials are most effective in wound care, which keeps the wound free from contamination, infection, or other external shocks. It is a clinical device, used for cleaning, covering, and shielding the wounds to facilitate healing

(Mao and Russell, 2004). A good dressing provides a positive environment to the wounds by maintaining the moisture balance that ultimately accelerates the wound healing process and increases the rate of epithelialization (Gates and Holloway, 1992; Percival, 2002). However, modern dressings, especially the active dressings, also encourage the production of granulating tissues in the wounds, keep the wound safe from environmental and bacterial contamination, and provide painless autolytic debridement (Hurd *et al.*, 2009) with minimal interference with the patient's life. Wound dressing materials promote the healing process through regeneration and repairing of dermal and epidermal tissues.

Wound dressings for treatment and management of infection

Dressings containing antimicrobial agents are a good option to prevent and eradicate wound infection. Silver is the most common antimicrobial that is used in wound dressings. Silver in elemental or compound form can be incorporated into the dressing materials by physical attachment or chemical treatment. A number of dressings based on ionic silver such as Silvercel, Actisorb Silver 220, Aquacel Ag, and Acticoat, etc. and silver compounds such as Urgotul SSD and Biostep Ag, etc. are available in the market. Most of the silver dressings are made of alginate, CMC, polyurethane foam, hydrogel, and hydrocolloid materials (Lindsay, 2011). However, iodine based dressings are also effective to reduce the bacterial load and infection from the wounds. Iodine is used in wound dressings as povidone-iodine (PVP-I) such as in Inadine (Systagenix) or cadexomer iodine such as in Iodosorb (Smith & Nephew). All of these dressings are found effective against wound infections. Hence, dressings containing antimicrobials along with antiseptics for cleansing of the wound are the most effective solution to manage infected wounds.

Wound dressings for treatment and management of exudates

Dressing is the most popular and effective tool to manage most wounds, both acute and chronic. A number of dressings are available in the market but the use of the right dressing for a selective wound is crucial. A low exuding or dry wound needs a dressing that can provide moisture to maintain the wound healing moisture balance. For example, hydrogel dressings can provide a moist-wound microenvironment to promote wound healing. However, chronic and infectious wounds with heavy exudates need a dressing with high absorption capabilities, for instance, alginate, hydrofiber, or foam dressings.

Management of exuding wounds is extremely difficult because of a number of factors that are associated with exuding wounds: The size and depth of the wound, the presence of infection, and the status of exudates. The status of the exudates includes type, amount, and viscosity, which are the key factors in choosing appropriate exudate management tools. Sustained release of poorly managed or unmanaged exudates may lead to serious problems. Thompson and Stephen-Haynes (2007) stated that "failure to manage exudate can lead to tissue saturation and leakage onto the surrounding skin with the potential to damage and prolong wound healing time." Using an appropriate absorbent dressing is the best option to handle the wound exudates.

The first recognized absorbent dressing, Gamgee, invented by Joseph Sampson Gamgee in 1880 (Gamgee, 1884), was made from bleached cotton and wool fibers to absorb high volume of exudates. However, cotton fibers may stick to the wounds, which leads to difficulty, discomfort, pain, or even further injury to the wound during removal of the dressing. These gauze based dressings had limited fluid retention ability and were not effective in providing a moist-wound environment. However, modern absorptive dressings such as alginate, hydrofiber, hydrocolloid, polysaccharide, and foam have overcome these limitations.

Wound dressings for treatment and management of malodor

There is no specific method to handle malodorous wounds but the use of appropriate antibiotics (usually metronidazole) or antimicrobial agents can prevent or decrease the wound infections that are mainly responsible for malodor in many cases (Houghton and Young, 1995; Thomas *et al.*, 1998; Paul and Pieper, 2008; Poteete, 1993). Poteete (1993) found that the use of 0.75% topical metronidazole gel to the wound surface is effective to reduce the wound malodor. Alternatively sugar paste and honey are also effective against bacteria especially the antibiotic resistant bacteria. Products with high sugar content have the ability to produce a hyperosmotic wound environment that restrains bacterial growth and assists in wound debridement (Molan, 1999; Naylor, 2002). Some wounds with the presence of large amounts of liquefying or sloughy tissues may cause a bad smell that can be absorbed and removed using a suitable absorptive dressing. Cleansing of the necrotic or sloughy tissues is an effective way to reduce the malodor from the wounds (Fletcher, 2008).

However, identifying the actual cause and taking appropriate action to diminish the cause are the key steps for successful management of wound malodor. In some cases, several factors are responsible for the bad smell and it is not possible to apply any specific strategy; simple actions such as good hygiene, cleansing and debridement, use of antimicrobials, use of specialist odor-absorbing dressing would be more appropriate and realistic to handle these wounds (Lee *et al.*, 2006; Fletcher, 2008; Lipman and van Bavel, 2007). However, in many cases the use of suitable odor absorbing dressings can give immediate results to minimize the wound malodor. These odor absorbing dressings are mainly based on activated charcoal cloth such as CarboFlex (ConvaTec), Lyofoam (SSL International), Actisorb Silver 220 (Johnson & Johnson Healthcare, Ascot), or cyclodextrins such as Exuderm OdorShield (Medline Industries, Inc).

Desirable Properties of a Wound Dressing

Selection of an ideal wound dressing is mostly dependent on the nature and depth of the wound. No single dressing developed yet is suitable for all kinds of wounds. The functions and efficiency of the dressings are mainly dependent on the materials being used

and the structure of the dressing. Moreover, structural features such as porosity in desirable size and shape, and appropriate mechanical strength suitable for supporting cell growth and proliferation should be considered in tissue regeneration technology from synthetic polymeric materials (Gunatillake and Adhikari, 2003). However, the ultimate objective of the dressings is to quicken wound healing with maximum comfort. The following properties are commonly expected from an ideal wound dressing product (Zahedi *et al.*, 2010; Ahamed *et al.*, 2010; Winter, 1975; Jones and Miguel, 2006):

- Nontoxic, nonallergic, nonsensitizing, nonscarring, and sterilized
- Ability to absorb and retain excessive wound exudates
- Providing moist microenvironment in the interface of wound surface and dressing
- Facilitating autolytic debridement to remove unexpected necrotic tissue and eschar, foreign objects, and contaminations from the wound
- Ability to protect from environmental contamination
- Ability to withstand normal mechanical shock/trauma/pressure
- Allowing gaseous and fluid exchange between wound and dressing
- Making a strong barrier for bacterial protection
- Easy removal of wound dressing fully without any pain or trauma
- Ability to absorb wound malodor
- Assisting regeneration of damaged tissue
- Providing thermal insulation
- Comfortable and conformable
- Long service life
- Available in different sizes and shapes
- Cost effective

However, it is expected that advanced dressings would perform not only the aforementioned functions but also interact with the wound to encourage healing. The dressings containing functional additives such as antimicrobials, growth factors, and inbuilt biosensory mechanisms can be more effective to enhance wound healing and repair (Sweeney *et al.*, 2012). In recent years, tissue-engineered fibrous substrates or scaffolds constructed from biomaterials have been focused as a key research area to develop smart wound dressing devices. Tissue-engineered dermal substitute and artificial ECM are such types of devices that are successful for repairing and regenerating the damaged tissue cells in unrepairable burns or chronic wounds.

Selection of a Wound Dressing

Selection of the right dressing at the right time is the key to success of wound healing. Before choosing a particular dressing for a particular wound one must have a clear understanding about the function of the dressing materials and how they work, and what factors influence the wound healing process. Baranoski and Ayello (2012) proposed the following wound care decision algorithm, which is effective for choosing the right dressing for a particular wound (Fig. 1).

Fig. 1 Wound care decision algorithm. Reproduced from Baranoski, S., Ayello, E.A., 2012. Wound Care Essentials: Practice Principles, third ed. Philadelphia, PA; London: Lippincott Williams & Wilkins.

Dressing Formats

Wound dressings can be in a variety of formats that include film, rope, ribbon, fiber, yarn, or fabric. The fabric forms woven, knitted, braided, and nonwoven are the most common. The structure of the wound dressing is important because the physical and mechanical properties of the dressing are mostly dependent on its structure. In many cases the functional properties of the wound dressing are dependent on its structure. The different formats of wound care dressings are briefly discussed below.

Fibers

Fibers are the fundamental materials extensively used in wound dressing in different forms. Fiber pads can be used to clean and cover wounds. Other formats of dressings are also produced from fibers. The diameter of the fibers can be from a few microns to a few millimeters. Practically, many fibers, categorized as below, are used in producing wound dressing products.

Degradable fibers: Cotton, viscose rayon, lyocell, wool, silk, bamboo, alginate, carboxymethylcellulose, chitin, chitosan, collagen, gelatin, etc.

Nondegradable fibers: Polyester, polyamide, polyethylene, polypropylene, polyurethane, polytetrafluoroethylene, etc.

Resorbable fibers: Poly(lactic acid) (PLA), polyglycolic acid (PGA), poly(lactic acid-co-glycolic acid), etc.

Specialty medical fibers: Super absorbent fibers, activated charcoal fibers, catgut, brananferulate, etc.

Yarns

The continuous form of twisted fibers or filaments is known as yarn. Usually, yarns are made from staple fibers or continuous filament, or combining both staple fibers and filament. Yarns are used to produce woven, knitted, and braided fabrics for dressings. However, the forms of thick yarn, rope, roving, and sliver can be used as wound dressing for specific wounds.

Woven fabrics

Woven fabrics for wound dressing are produced in sheet form using two sets of yarns, warp and weft. The woven structure is comparatively inexpensive and dimensionally stable, and easy to handle. This structure is commonly seen in gauze fabric. The woven structure of fabric can also be used as a base or support structure of other formats of dressing ([Fig. 2](#)).

Knitted fabrics

Knitted fabrics are comparatively soft, flexible, and more drapable than woven fabrics. However, the higher porosity and dimensional instability are the major limitations of knitted fabrics as wound dressings.

Braided fabrics

Braided fabrics are used when a dressing with small diameter is necessary. These fabrics are mechanically stable like woven fabric, but more flexible and conformable than woven fabrics ([Gupta and Edwards, 2009](#)).

Nonwoven fabrics

Nonwoven fabrics are the most common in wound dressing products. These fabrics are soft, woolly, and more resilient than woven or knitted fabrics. Importantly, the production method of nonwoven fabrics is simple and inexpensive because these fabrics are made directly from fibers. These fabrics are suitable for producing absorptive dressings that are effective in absorbing large amounts of wound fluids.

Nanomaterials

Nanofibers from biocompatible natural and synthetic polymers are used to produce dermal substitute, tissue engineered skin, scaffold, and implantable devices. A number of studies ([Chong et al., 2007](#); [Venugopal and Ramakrishna, 2005](#); [Li et al., 2002](#)) have reported that nanofibrous matrixes from biocompatible materials promote cell attachment, adhesion, growth, spreading, and proliferation. Electrospinning is the most simple and effective method to produce such kinds of nanofibrous matrixes that mimic the ECM of natural tissue. Moreover, some nanomaterials such as silver, carbon, copper, zinc, etc. can be incorporated into the fibers, yarns, or fabrics to make more efficient and multifunctional wound dressings ([Mao and Russell, 2004](#)).

Classification and Structures of Wound Care Dressings

Depending on the functions, wound dressings can be classified as inert/passive, interactive, and bioactive dressing. However, according to their uses wound dressings can be classified as primary dressing, which is placed in contact with skin, and secondary dressing, which is used as a supportive layer or cover over primary dressings. A summary and the functions of these dressings in wound applications are presented below ([Zahedi et al., 2010](#); [Jones and Miguel, 2006](#); [Miraftab, 2006](#); [Mao and Russell, 2004](#); [Hoekstra et al., 2002](#)).

Inert/passive dressings

The inert wound dressing encompasses gauze, lint, and tulle, which are usually used to cover the wounds. These materials are mainly used on lightly exuding wounds to keep them safe and free from contamination and infections. These types of

Fig. 2 Different dressing formats: Fibers web (A), roving or sliver (B), woven structure (B), knitted structure (D), nonwoven structure (E), and rope or braid structure (F).

dressings help to rehabilitate the wounds beneath the dressing materials, but are not usually used as a primary dressing. The modified inert dressings, for example, EXU-DRY (Smith & Nephew) dressing, can be used as secondary dressing over moderate to highly exuding wounds over primary dressings (Weller and Sussman, 2006). When an inert dressing, for instance, cotton, is used as primary wound dressing this may adhere to the wound and cause trauma on removal. However, modern synthetic fiber meshes, for instance, Adaptic, Cuticerin, or Atrauman (Cutting and White, 2004b) can be good alternatives to conventional inert dressings. They can maintain moisture balance in the wound and reduce the distortion of the wound and tissues.

Gauze

These are mainly lightweight normal woven fabrics with loose plain weave or sponge suitable for covering different wounds including minor injuries, burns, and surgical wounds. They are usually inert sterile substances such as gauze pads, gauze rolls, gauze sponges, gauze dressing made from cotton, viscose rayon, polyester, or combination of these fibers. Since these gauzes can easily stick to the wounded skin they are mainly used as secondary dressing. However, they can also be used as primary dressings especially for exuding wounds. The gauze dressings are categorized as impregnated dressings, wrapping gauzes, and sponges. Impregnated gauze dressings are usually saturated with petroleum jelly, oil, paraffin, hydrogel, antiseptics, or antimicrobials. The gauze impregnated with petroleum and hydrogel maintain a wet healing wound environment that promotes the healing process. The gauze is impregnated with white or yellow colored liquid paraffin to provide nonadherence and semiocclusive characteristics. These gauze dressings can also be medicated or impregnated with antiseptics such as povidone iodine, chlorhexidine, and sodium fusidate for providing resistance to microbial contamination. Wrapping gauzes are usually made from cotton, elastic, and nylon, and mainly used for securement, padding, and protection of wounds from external shocks and contamination. Sponges are mainly gauze pads folded into a square.

Tulle

Gauzes with grease or petroleum that do not stick to the wound surface are suitable for flat or shallow wounds. Functional materials such as honey and iodine solution can be added with the tulle to incorporate functional properties. Jelonet, Bactiqras, and Activon Tulle are such examples available in the market.

Transparent film dressing

Transparent film dressings are actually transparent sheets supported by an adhesive backing, made of polyurethane. Although they allow moisture, air, and oxygen to pass, they prevent penetration of liquids and microorganisms. They are usually used on partial-thickness or minor wounds including intravenous sites, lacerations, abrasions, wounds with minimal exudates, and second-degree burns (Gupta and Edwards, 2009). Due to their transparent characteristics they are suitable for following-up and inspection of covered wounds without removing the dressing.

Interactive dressings

The interactive dressings are mainly polymeric films, and/or foams that maintain the moist-wound healing environment and positively interact with the wound surface. These dressings facilitate wound healing by exchanging vapor and atmospheric oxygen with the wound. These polymeric dressings not only assist the wound healing but also protect the wound from bacterial attack and contamination. A large spectrum of wounds from minor injury to complex wounds can be handled by using these dressings.

Semipermeable films

Semipermeable films are made from polyurethane, and they are suitable for superficial, low exuding wounds. These thin and transparent films allow moisture and oxygen but protect against bacterial contamination. They can be attached to the dry or slightly exuding wound surface with acrylic adhesive. They are suitable as a primary dressing but can also be used as a secondary dressing over alginate or hydrogel dressings. For example, Tegaderm (3M, Bracknell), OpSiteFlexigrid (S&N, Hull), Mefilm (Molnlycke Health Care), etc. are some common commercial semipermeable film dressings available in the market.

Semipermeable foams

These are polyurethane or silicone based soft foam, adhesive or nonadhesive, absorbent, flexible, conforming, moisture retentive dressings suitable for moderate to highly exuding wounds. They allow oxygen and provide thermal insulation to the wounds. They are usually used as a primary dressing. For example, Allevyn (S&N), Versiva XC (ConvaTec), Lyofoam (Seton Healthcare), etc. are some commercial semipermeable foam dressings available in the market.

Hydrogel dressing

These dressings consist of an insoluble polymer matrix that contains water and other ingredients to maintain wound healing moisture balance. They provide comfort and rehydration to the dry wounds, and facilitate removal of dead tissues from the wounds. They are usually used as a primary dressing, and are easily removable from the wound bed. For example, Aquaform gel (Unomedical), Intrasite gel (S&N), Nu-gel (Systagenix), etc. are some commercial hydrogel dressings available in the market.

Hydrocolloid dressing

These polyurethane based wafers contain hydrocolloid particles such as Na-CMC, gelatin, and pectin that absorb exudates and are converted into gel. They are suitable for lightly to heavily exuding, sloughing, or granulating wounds. They are usually used as a primary dressing. For example, DuoDerm (ConvaTec), Tegaserb (3M Company), Comfeel Plus (Coloplast), etc. are some commercial hydrocolloid dressings available in the market.

Bioactive dressings

Bioactive wound dressings are multifunctional and made from functional bioactive materials such as alginates, hydrofibers, collagens, hyaluronic acid, chitosan, etc. These dressings contain functional ingredients such as silver antimicrobial, growth factor, and ECM components to achieve advance functionalities. They can meet almost all the requirements to be an ideal wound dressing. They promote the healing process and provide internal cell regenerating environment for wound closure. They are remarkably effective for treating acute and chronic wounds compared with other dressings. They can even administer antibiotics.

Alginates dressing

These highly absorbent (absorbency is about 15–20 times of their dry weight) biocompatible dressings maintain a physiologically moist microenvironment that promotes wound healing and the formation of granulation tissues in the wound. When the calcium alginate fibers of wound dressing come in contact with exuding wounds they absorb the exudates and form sodium alginate gel by ion exchange reaction between the calcium ions of alginate fibers and sodium ions of sodium salt of wound fluids. The gel provides a moist wound environment that is desirable for wound healing and reepithelialization.

Moreover, it is believed that the calcium ions stimulate platelet aggregation and coagulation to assist blood clotting, that is, hemostasis (Mao and Russell, 2004; Blaine, 1947), which reduces blood loss and shortens the healing time (Barnett and Varley, 1987). Thus, the alginate dressing is suitable for hemostasis, exudate absorption, and providing moist-wound environment to the wound. For example, Kaltostat (ConvaTec, UK) is a calcium sodium alginate (80% Ca: 20% Na) nonwoven dressing derived from

the brown kelp *Laminaria hyperborean* (Vanstraelen, 1992). It is capable of absorbing large amount of fluid when it comes in contact with wounds; the fibers gradually convert into a viscous, nonadherent gel-like product that maintains wound healing moist environment and allows trauma-free removal of the dressing from the wound.

Incorporation of functional ingredients such as silver antimicrobial with alginate dressing would provide additional benefits. Alginate dressings are suitable for moderate to high exuding wounds and they help in the debridement of necrotic tissues. They are usually used as primary dressing. Kaltostat (Convatec), Sorbsan (Unomedical), Algisite Ag (Smith & Nephew), etc. are some examples of alginate based commercial dressings available in the market.

However, alginate dressings have some drawbacks. First, they may dehydrate the wounds, which can negatively affect the healing process. Second, they have structural instability after gel formation, which may lead to difficulty in removing the dressing from the wound. Third, they have limited fluid retention capacity. The alginate dressings are not suitable for dry or low exuding wounds as they make the wound more dehydrated. Moreover, when alginates convert into gel after absorbing the exudates they attain a loose form that is difficult to handle. Besides, alginate fiber has limited retention ability compared with Na-CMC fiber, which may cause maceration in the fresh skin around the wound.

Hydrofiber dressing

These are nonwoven soft pads or ribbons made from sodium carboxymethyl cellulose fibers. When these fibers come in contact with wound fluids they absorb large amount of fluids and convert into soft gel. These high absorbent dressings are suitable for a wide range of acute and chronic deep wounds. They can maintain wound healing moisture balance and absorb harmful components from the wound to accelerate the healing process. For example, Aquacel (Convatec), Aquacel Ag (Convatec), Versiva (Convatec), etc. are some commercial hydrofiber dressings available in the market.

Collagen dressing

These are gels, pads, particles, pastes, powders, sheets, or solutions derived from bovine, porcine, or avian sources. They are suitable for exuding wounds like ulcers, burns, surgical wounds, etc. They not only promote wound healing but also assist regeneration of new tissues because the collagen acts as a structural scaffold for tissues. They can be used as primary and secondary wound dressings. For example, Biostep Ag is a collagen based commercial dressing.

Chitosan dressing

Chitosan is a biocompatible material that is used as solution, gel, sponge, film, or nonwoven material in wound care products. It has natural antibacterial and hemostasis effects. Due to limited spinnability the chitosan fibers can be blended with other fibers such as polypropylene and viscose to form dressing structures. For example, Chitopack C (Eisai Co), Tegaderm (3M Company), Chito-Seal (Abbot), etc. are some chitosan based commercial dressings available in the market.

Composite dressing

Composite wound dressings are the combination of different dressings that provide several functions depending on the constituent materials and structure. Usually, composite wound dressings consist of multiple layers, commonly three layers, including a semi- or nonadherent skin contact layer that adheres to the wounds with help of an adhesive border. The outermost layer protects the wound from bacterial invasion and allows air to circulate. However, an absorptive layer, in between the skin contact layer and outermost layer, is composed with absorptive materials such as CMC, alginate, polyacrylate, etc., which maintain the moisture balance of wounds. These dressings can be used as a primary and/or secondary dressing for both acute and chronic wounds. They are versatile and suitable for a wide range of wounds that includes minor injuries, low to heavy exuding wounds, ulcers, and surgical wounds.

Foam dressing

Foam dressings are usually made of semipermeable polyurethane foam with small, open cells that can absorb and hold liquids into air-filled spaces by capillary action. Silicone based foam dressing is also used as an adhesive wound contact layer. This foam can be applied as a layer to another structure for obtaining better features. Due to their porous structure they can absorb and retain a huge amount of liquid from their surroundings. They can protect the wounds from external shocks and discomfort. These dressings are very effective in managing heavily exuding and odorous wounds but are not appropriate for dry wounds. However, these dressings are suitable for managing both acute and chronic wounds of both partial- and full-thickness wounds. Foam dressings are produced with a variety of thickness and shapes containing adherent or nonadherent and nonlinting skin contact surface. These dressings are usually soft and flexible supported by a silicone adhesive, which helps the dressings to stay on the wounded place. They are very easy to use and easy to remove and fulfill most of the criteria of an ideal dressing used in moist wound healing. They can be easily cut in appropriate size to fit irregular wounds and curve areas. The hydrophobic and waterproof outer surface of foam dressings keeps them safe from bacterial and external contamination. Sometimes, the foam dressings are functionalized incorporating therapeutic elements such as silver, Manuka honey, cadexomer iodine, antibiotics, etc. Production, storage, and application and removal from the wound are very easy and simple.

Table 1 Silver-loaded commercial dressings

Dressing	Antimicrobial ingredient	Dressing construct	Manufacturer
Acticoat absorbent	Ionic silver	Calcium alginate	Smith & Nephew, Inc.
Actisorb Silver 220	Ionic silver and charcoal cloth	Silver impregnated charcoal cloth	Johnson & Johnson Medical Ltd
Aquacel Ag	Ionic silver	Hydrofiber	ConvaTec Ltd
Contreet H	Ionic silver	Hydrocolloid	Coloplast Corp
Silvasorb	Ionic silver	Hydrogel sheet or amorphous gel	Medline Industries, Inc.
Silvercel	Ionic silver	Alginate and CMC based nonwoven pad	Systagenix
Optifoam Ag	Ionic silver	Absorbent foam	Medline Industries, Inc.
Biostep Ag	Silver chloride	Collagen matrix	Smith & Nephew, Inc.
Urgotul SSD	Silver sulfadiazine	Polyester mesh	Laboratories Urgo

Note: Ovington, L.G., 2007. Advances in wound dressings. *Clinics in Dermatology* 25 (1), 33–38. Lindsay, S., 2011. Silver White Paper. Available at: <http://www.systagenix.com.br/media/originals/20120412-101643-8910.pdf> (accessed 03.02.19).

Silver-Loaded Dressings

Silver-loaded dressings are effective and widely used to control a large spectrum of microbial wound infections. Depending on the demand of a wound condition the silver content in the dressing may vary as high, medium, or low. Qin (2009) stated that high silver content dressings provide rapid release of silver that is necessary for the wounds with high infection and bacterial colonization. The dressings with medium content of silver provide sustained release of silver over several days and are effective for treating wounds with moderate to high infection and bacterial colonization. Dressings with low silver content are useful to treat wounds with minimal infection in chronic wounds as well as to prevent infection in acute wounds, burns, and surgical injuries. The silver ions can be incorporated into the wound dressings by the following three general methods (Qin, 2009):

- Physical treatment. In this method the fiber or fabric of the dressing are coated with metallic silver.
- Chemical treatment. The dressing materials are treated with silver solution; an ion exchange reaction occurs. As a result, the silver ions are attached to the fiber or fabric of the dressing.
- Blending. In this method fine particles of silver compounds are blended with the dressing materials.

A number of silver dressings based on alginate, CMC, films, hydrogel, hydrocolloids, polyurethane foams, and charcoal cloth, etc. are available in the market (Karlsmark *et al.*, 2003; Ovington, 2007; Lindsay, 2011). Table 1 includes some prominent silver-loaded wound dressings available in the market.

Malodor Absorbing Dressings

Dressings with the ability to resolve the causes (e.g., infection) of wound malodor are the most effective way to handle wound malodor. However, the dressings containing odor absorbing ingredients such as charcoal and cyclodextrins are effective for capturing and controlling the volatile malodorous molecules from the wounds. Activated charcoal as charcoal cloth has been used successfully in wound dressing to adsorb and bind the molecules responsible for malodor. However, charcoal cannot function when it is saturated with wound exudates. Hence, charcoal based dressings are not suitable for an exuding environment, which is common in most malodorous wounds.

During the last few decades a number of charcoal-based odor absorbing dressings have been introduced in the market. Since wound malodor is correlated with microbial infection and the presence of sloughy tissues or exudates, the absorptive dressings containing antimicrobials and odor absorbing components would be more effective than a single odor absorbing dressing. In some commercial dressings, for instance, Actisorb, which is the first charcoal-based dressing, introduced by Johnson & Johnson Medical Ltd, the charcoal bed is used to achieve additional benefits with exudates absorbability. The improved version of Actisorb is Actisorb Silver 220, which is a sterile multifunctional wound dressing formed from a composite structure that includes an activated charcoal cloth in a spun bonded nylon envelope. The charcoal cloth is impregnated with 0.22% w/w elemental silver (Lindsay, 2011).

Besides charcoal, cyclodextrins have the ability to entrap the volatile molecules responsible for wound malodor. Cyclodextrins have a cavity (host) in their structure and the targeted molecules (guests) are enclosed into the cavity. The effectiveness of this inclusion depends on the size of host cavity and guest molecules. Thus, the mixture of common cyclodextrins with different cavity sizes, α CD, β CD, and γ CD, incorporated with dressing material are capable of capturing the optimum number of malodorous molecules present in wounds (Lipman and vanBavel, 2007). Hence, cyclodextrins based dressings, for instance, ExudermOdor-Shield (Medline Industries, Inc.), have been introduced into the market. They are effective in capturing the malodorous molecules from the exuding wound environment (Medline, 2007). Table 2 shows some odor absorbing commercial dressings.

Nanofibrous Dressings and Skin Substitute

Due to their high specific surface area and microporous structure, electrospun nanofibrous mats can be used as an interactive wound dressing that is able to quickly start signaling pathways and attract fibroblasts to repair damaged tissues in the wound

Table 2 Odor absorbing commercial dressings

<i>Dressing</i>	<i>Odor absorbing ingredients</i>	<i>Dressing construct</i>	<i>Manufacturer</i>
Actisorb Plus	Charcoal cloth (CC)	Consists of a CC of 95%–98% carbon, produced from knitted viscose rayon fabric. The rayon fabric is enclosed in an envelope of spun-bonded nonwoven nylon.	Johnson & Johnson Medical Ltd
Actisorb silver 220	Charcoal cloth (CC)	Consists of silver impregnated CC. This dressing contains 220 mg silver per 100 g activated charcoal cloth.	Johnson & Johnson Medical Ltd
CarboFlex	Charcoal cloth (CC)	Multilayered dressing consists of alginate and CMC fibers wound contact layer. A plastic film beneath the CC is placed between the wound contact layer and an absorptive layer on top.	ConvaTec Ltd
Lyfoam C	Charcoal granules (CG)	A nonwoven fabric along with CG is enclosed with two pieces of polyurethane foam, bonded together around the perimeter.	Seton Healthcare
Carbonet	Charcoal cloth (CC)	Multicomponent dressing consists of knitted viscose wound contact layer backed with a cellulosic absorbent layer and a charcoal cloth layer. This assembly is sandwiched between two layers of polyethylene net.	Smith & Nephew Medical
Sorbsan plus carbon	Charcoal cloth (CC)	Multilayered absorptive dressing consists of CC cloth and an alginate fibrous wound contact layer.	Pharma-plast Ltd
Exuderm OdorShield	Cyclodextrins (CDs)	Hydrocolloid substance with the mixture of α -, β -, γ -CDs	Medline Industries, Inc.

(Ed.), *Handbook of Medical Textiles*. Woodhead Publishing.

(Chen *et al.*, 2008; Chung *et al.*, 1994). These materials provide the necessary mechanical strength and stability in three dimensions to allow cells and tissues to colonize and regenerate the damaged or missing skin/organs, which ultimately enhances wound healing and repair (Mirafteb, 2006). Nanofibrous scaffolds have been successfully used to repair and restore the damaged skin especially burn injured skin. Numerous studies (Zahedi *et al.*, 2010; Chen *et al.*, 2008; Chung *et al.*, 1994; Khil *et al.*, 2003; Chong *et al.*, 2007) have reported about the effectiveness, functions, and advantages of nanofibrous wound dressings. The functions and advantages of nanofibrous dressings are presented below.

Hemostasis

The nanofibrous dressing material closely adheres with the wound surface and blocks the spilling of blood more successfully compared with other conventional wound dressing materials. In the wound healing process, they act as a hemostatic agent to promote bleeding off.

Absorbability

As the nanofibrous materials are fluffy and porous they can absorb wound liquids effectively. Due to high surface area-to-volume ratio they show 17.9%–213% water absorption, which is significantly higher than conventional film dressings (Dabney, 2002). Thus, the nanofibrous dressing materials can manage heavy exudates more effectively compared with their counterparts.

Semipermeability

The nanofibrous mesh acts as a semipermeable membrane that allows the atmospheric oxygen into the wound but prevents access of harmful substances, bacteria, and viruses. This can also maintain the moisture balance of the wound, which promotes wound healing.

Effective wound coverage

The maximum coverage and contact of the wound surface with dressing material are influenced by the fineness of constituent fibers. As the fibers of nanofibrous dressing are very fine and flexible, they can easily conform to the contour of a wound. Thus, a nanofibrous mesh can easily fit and conform to any complicated outlines of wounds.

Functional ability

In recent years, multifunction wound dressings are constructed to achieve high quality wound management for both patients and clinicians. Incorporation of functional ingredients with bioactive nanofibrous material can provide advanced functional properties in wound dressing. Depending on the necessity, functional drugs such as antibiotics; active pharmaceutical components such as antimicrobial, vasodilators (e.g., minoxidil for promoting wound epithelialization and neovascularization); growth factors (e.g., FGF, EGF, and TGF); and cells (e.g., keratinocytes) can be incorporated into the nanofibrous substrates.

Table 3 Nanofibrous based commercial dressings

Dressing	Dressing construct	Manufacturer
Tegaderm	Poly(ϵ -caprolactone) (PCL)/gelatin nanofibrous scaffold is directly electrospun onto a polyurethane dressing to form dressing construct	3M Company
Biobrane	Highly purified peptides derived from porcine dermal collagen is bonded to the nanofibrous nylon/silicone membrane	Smith & Nephew
ChitoFlex	It is fabricated from chitosan nanofibers, which are effective to stop bleeding	HemCon Med. Tech. Inc
Permacol	Dermal collagen matrix of porcine nanofibers	Covidien
DermaFuse	It is composed of borate glass nanofibers	Mo-Sci Corporation
Apligraf	It consists of bovine collagen nanofibrous sponge with living cells (fibroblasts) and structural proteins (keratinocytes)	Noveris
Integra	It is a biodegradable porous matrix made from collagen-glycosaminogly as main component	Integra Life Sciences
TransCyte	Composed of human newborn fibroblasts, which are then cultured on the nylon nanofibrous mesh	Advanced Tissue Science

Scar-free

Although it is difficult to achieve wound healing without leaving any scar, the nanofibrous wound dressing can heal the wounds with minimal scar. Electrospun bioactive fibrous mesh allows the regeneration of epithelial cell in its structure, which facilitates the forming of natural ECM from the inside of the wound to replace the dead or damaged tissues. Incorporation of antibacterial agents with these substances provides double action: Bactericidal effect and reformation of wound tissues that ensure quick wound healing without producing large amounts of scarring. Table 3 shows some commercially available nanofibrous wound dressings.

Conclusions

Wound dressings are the primary choice for wound care and management. A large number of wound care dressings are available in the market both for acute and chronic, full or partial-thickness wounds. The dressings are made of different polymeric and fibrous substances originated from natural or synthetic sources. Some of the fibrous substances are inert in function and some of them have intrinsic functional properties. The fibrous materials such as alginate, carboxymethylcellulose, collagen, chitosan, PLA, PGA, etc. have additional functional characteristics that make them suitable for producing advanced wound care dressings. Moreover, the specific therapeutic or medicinal agents such as antimicrobials, growth factors, vitamins and mineral supplements, etc. can be incorporated to these dressings to promote the healing process. At present, wound care professionals have a wide range of options to choose the right dressing from simple cotton gauzes to high-tech multifunctional dressings, and even skin substitutes. However, an ideal dressing to treat and manage large number of wounds specifically chronic wounds has not been developed yet.

PREFACE

The *Encyclopedia of Renewable and Sustainable Materials* is a novel initiative, launched to cater for researchers, industrial practitioners and environmental conservationists to bring to the fore the issues of renewability, regeneration, recyclability and sustainability of natural material resources for the greater good of the environment, society and renewable resources. With these objectives the project was constituted of 11 sections, led by one Section Editor each. There are about 4,000 printed pages, accommodated in five volumes ranging from 600 to 1000 pages each.

This encyclopedia is the primary reference source for researchers at different levels and stages in their career in academia and industry and those with an interest in environmental protection and sustainability, including re-use and recycling of natural and synthetic materials and regeneration of natural materials. The work encompasses the knowledge and understanding of many experts into a single, comprehensive work of about 370 articles comprising a combination of review articles, case studies and research findings resulting from research and development activities in both industrial and academic domains. The encyclopedia, focuses on how some of these topics bring advantages for a broad range of technologies and environmental protectionists. These include harnessing existing materials both natural and synthetic, their re-usability and regeneration possibilities for the greater good of society and the environment. The aspects of feasibility, conservational objectives and practicability of implementation have been addressed through a number of relevant articles.

As Editors in Chief of this five-volume comprehensive publication, a truly collaborative work, we are greatly indebted to the 11 Section Editors who are internationally renowned experts in their fields, for guiding and selecting the topics for their respective sections which constitute the five volumes, commissioning authors and reviewing the contents so meticulously. Their true dedication to the scientific community and society is reflected in the time and energy they have given to this project. My sincerest thanks are due to all the authors – researchers, environmental protectionists and practitioners who have contributed extensive coverage of literature review as well as recent works of research to this substantial five volume encyclopedia. The excellent insight and specialist knowledge in their respective fields is reflected in the high quality content of this unique work.

Both of us and all the section editors are greatly appreciative of all the hard work undertaken by all concerned to turn this concept of the *Encyclopedia of Renewable and Sustainable Materials* into a publishable work. Our special thanks go to Ruth Rhodes and Michael Nicholls, the Project Manager, along with Kshitija Iyer and the rest of the team at Elsevier who served successively to keep the project on track through friendly nudges in order to ensure timely completion. We are also hugely grateful to other colleagues at Elsevier production unit for the coordination of the proofs.

The extensive research treatment of core ethos of renewability, recyclability and regeneration, supplemented by applied case studies has drawn together many areas of research and we sincerely hope that this work will prove to be of great help to both the young and experienced members of the international research community, academics and industrial practitioners associated with sensible utilization of natural and synthetic materials for many years to come.

Saleem Hashmi and Imtiaz Ahmed Choudhury
Editors in Chief – *Encyclopedia of Renewable and Sustainable Materials*

CONTENTS OF VOLUME 3

Editorial Board	v
List of Contributors to Volume 3	vii
Preface	xiii

Renewable and Sustainable Materials in Automotive and Consumer Products and Packaging

Application of Nanofluids for Radiator Cooling <i>Sudhakar Subudhi and Aditya Kumar</i>	1
An Assessment of Hydrogen Energy Utilization for Sustainable Development <i>Ahmet Z Sahin</i>	10
Bacterial Cellulose Based Nanocomposites for Electronic and Energy Applications <i>Sreeja K Sathish and Satish Vitta</i>	16
Biodegradable Packaging <i>Rajinder K Dhall and Mohammed S Alam</i>	26
Bio-Polymeric Packaging Material for Packaging of Raw Food <i>Sasmita Majhi, Anju Tyagi, and Abhijit Mishra</i>	44
CO ₂ Capture, Storage, and Enhanced Oil Recovery Applications <i>Muhammad Sagir, Muhammad Mushtaq, Muhammad S Tahir, Muhammad B Tahir, Sami ullah, Naeem Abbas, and Muhammad Pervaiz</i>	52
Development of Self-Adhesive Products Using Only Bamboo Fibers Extracted With a Machining Center <i>Keiji Ogawa, Toshiki Hirogaki, Eiichi Aoyama, and Hiromichi Nobe</i>	59
Effect on Compounding Process in Natural Rubber for Sustainable Suspension Materials <i>Mohd A Salim, Adzni M Saad, and Intan RA Rosszainily</i>	71
Experimental Investigations for Friction Stir Welded 3D Printed Dissimilar Thermoplastics With Consumable Tool <i>Ranvijay Kumar, Rupinder Singh, and Inderpreet S Ahuja</i>	79
Impact Behaviors of Acrylonitrile Butadiene Styrene and Polylactic Acid Materials for Topological Industries <i>Mohd A Salim, Adzni M Saad, and Zarif H Termiti</i>	83
Joining of 3D Printed Dissimilar Thermoplastics With Consumable Tool Through Friction Stir Spot Welding: A Case Study <i>Ranvijay Kumar, Rupinder Singh, and Inderpreet S Ahuja</i>	91
Joining of 3D Printed Dissimilar Thermoplastics With Friction Welding: A Case Study <i>Ranvijay Kumar, Rupinder Singh, Inderpreet S Ahuja, and Kamal N Karn</i>	97
Joining of 3D Printed Dissimilar Thermoplastics With Nonconsumable Tool Through Friction Stir Welding: A Case Study <i>Ranvijay Kumar, Rupinder Singh, and Inderpreet S Ahuja</i>	109
Mechanical and Transmissibility Effect on Recyclable Suspension System for Different Loading of Carbon Black <i>Mohd A Salim, Adzni M Saad, and Intan RA Rosszainily</i>	114

Natural Oils as Green Lubricants in Forming Processes <i>Abdulaziz S Alaboodi</i>	122
Natural Oils as Green Lubricants in Machining Processes <i>Sounak K Choudhury and Muhammed Muaz</i>	129
Oil Palm Kernel Shell – A Potential Sustainable Construction Material <i>Timothy ZH Ting, Muhammad E Rahman, Hieng H Lau, Matthew ZY Ting, and Vikram Pakrashi</i>	137
Recyclability of Packaging Materials for Domestic Applications <i>Kamaljit S Boparai and Rupinder Singh</i>	144
Recycled Polypropylene-Nanoclay Composites – Mechanical Properties <i>Mohd H Othman</i>	149
Recycling and Downstream Processing of Aluminium Alloys for Automotive Applications <i>Brij K Dhindaw, Gowrawaram SL Aditya, and Animesh Mandal</i>	154
Renewable and Sustainable Materials in Automotive Industry <i>Manojit Ghosh, Arkajit Ghosh, and Avinava Roy</i>	162
Renewable Biofuels and Their By-Products for Automotive Applications <i>Shailendra K Shukla</i>	180
A Review of the Value-Added Chemicals and Materials From Bio-Based Lignin Feedstocks <i>Maryam Akbari, Adetoyese O Oyedun, and Amit Kumar</i>	187
Sustainable Air-Conditioning <i>Rehan Khan, Ritunesh Kumar, and Nirupam Rohatgi</i>	201
Toward Reclamation of Fibrous Waste Stream Materials <i>Marlann M Patterson</i>	219
Utilization of Bio-Hydrogen in HCCI Engines as a Most Renewable Fuel for Sustainable Transportation – A Thermodynamic Analysis <i>Abdul Khaliq, Faizan Ahmad, and Faizan Khalid</i>	224
Mitigating Greenhouse Effect and Carbon Footprint Through Renewability Approach	
Advanced Vehicle Systems and Technologies: Economic and Environmental Implications <i>Trina Dutta and Gautam Majumdar</i>	232
Advances in Surface Engineering for Improved Energy Storage <i>Rishav K Baranwal, Nisantika Biswas, Buddhadeb Oraon, and Gautam Majumdar</i>	245
Alternate Photovoltaic Material: Its Environmental Consequences <i>Soumitra Kar and Sunanda Dey</i>	250
Application of Remote Sensing in Wind Resource Assessment <i>Siraj Ahmed and Prem K Chaurasiya</i>	265
Biomass for CO ₂ Sequestration <i>Andrew C Eloka-Eboka, Joseph K Bwapwa, and Semakula Maroa</i>	277

Introduction

Vehicle engine thermal management is important to make the vehicle system more efficient and sustainable. Going into the brief history of the evolution of car and truck radiator cooling, it was found that a number of generation has been evolved in order to improve and maximize the efficiency of engine cooling. To improve the efficiency, air cooling was shifted to water because of its availability and ability to absorb and carry heat efficiently. However, Water has its limit of operating temperature range and inability to provide corrosion resistance. In order to improve its properties additives and other fluid like ethylene glycol has been added. In order to improve thermal properties more, the researcher focused on the addition of solid particles which have higher thermal properties into the conventional coolant called as nanofluids (Saunders, 1936). Nanoparticles can be dispersed in any of the liquid in that way it should fulfil requirement of thermal properties like viscosity, specific heat, density, thermal conductivity, surface tension, stability in the operative environment. However, the choice of base fluid in engine cooling system for enhancing heat transfer needs capabilities like high boiling and low freezing point, high thermal conductivity, high heat capacity etc. Base fluids such as water, ethylene glycol, mixture of water and ethylene, oil etc. are preferred in the cooling system. Some additives added into the conventional coolants to enhance the heat transfer characteristics. The additives were used to prevent corrosion on the engine wall and overheating and freezing of the coolants. The properties of conventional coolant water, Ethylene glycol (EG) and mixture of water and EG measured experimentally by Conrad *et al.* (1940), Tsierkezos and Molinou (1998) and Sun and Teja (2003) are given in Tables 1 and 2.

Lately, Micali *et al.* (2018) used the CuO nanoparticles into the engine coolant (pure water) and found that at 2.5 vol% of nanoparticles the reduction of temperature is 13.6% compared to water in the exhaust valve seat at 100% full load. Moghaieb *et al.* (2017)

Table 1 Thermal properties of water, ethylene glycol and mixture of water and ethylene glycol

Properties/ EG + Water	$X=0$ (Water)	$X=0.25$	$X=0.50$	$X=0.75$	$X=1$ (EG only)
Density (kg/m ³)	998	1068	1094	1106	1120
Viscosity (mPa s)	1.001	3.69	7.61	12.3	19.1

Fig. 1 Two step method to prepare Nanofluid.

investigated the characteristics of heat transfer for alumina water nanofluid and found that maximum enhancement in the heat transfer is 78.67% with 1 vol% concentration of nanoparticles into the water. The heat transfer analysis on the nanofluids comprised of different material nanoparticles in water and ethylene glycol are widely investigated (Darabi *et al.*, 2015). Sahin *et al.* (2013) investigated the turbulent convective heat transfer inside a circular tube and found that increasing heat volume concentration of nanoparticles into the base fluid enhanced the heat transfer. Furthermore, the viscosity also increased with the concentration which leads to increment of the friction factor. Raveshi *et al.* (2013) taken alumina nanoparticles dispersed in water and mixture of water and and ethylene glycol and stated that the optimum volume concentration of nanoparticles is 0.75% with a 64% maximum boiling heat transfer.

In this article, a comprehensive review of nanofluid focusing on engine cooling is compiled thoroughly for the researchers working in this field. The paper provides the recent developments in this field and facilitates researchers to find a latent research gap to develop new techniques for enhancing the overall efficiency of the heat transfer system. The article begins with the first section which explains existing synthesis techniques of nanofluids the next section contains the effect on the thermal properties of the various parameter of nanofluids followed by last section concluding the convective heat transfer analysis on the vehicle radiators or cooling system with nanofluids.

Preparation of Nanofluids

Nanofluids are generally consist suspension form of solid nanoparticles. Solid nanoparticles typically made out from the materials having higher thermal conductivity like metals. Thermophysical properties like thermal conductivity, viscosity, specific heat and density plays a vital role to enhance the heat transfer capability of the base fluids (Khurana *et al.*, 2016a,b). Metals, metal oxides, non-metals, carbon based materials and some organic materials having high thermal conductivity are used to synthesis nanofluids. Number of ways are there to synthesis nanofluids broadly categorised into two approaches which are one step method and two step method. The two step method include two steps to prepare nanofluids, first step to prepare dry nanopowder from the available physical or chemical techniques the second step consist dispersion of previously prepared nanopowder into the base fluid with the help of magnetic stirrer and ultrasonic sonicator, shown in Fig. 1. One step method includes simultaneous making and dispersion of nanoparticles into the basefluids. The Submerged arc nanoparticle synthesis system (SANSS) is one step method to prepare nanofluids shown and explained in Fig. 2 (Lo *et al.*, 2007). The one step method sidesteps the drying, storage and transportation of nanoparticles. However, one step has advantages over two step method but researchers prefer two step because it is easy and simple. Table 3 shows the summary of methods used to prepare nanofluids.

Nanofluid Thermophysical Properties

The nanoparticles colloidal suspension into conventional base fluid can modify the thermophysical property according to the desired requirement (Kumar and Subudhi, 2018). The idea behind using a colloidal suspension is to enhance the thermal conductivity of the

Fig. 2 Submerged arc nanoparticle synthesis system (SANSS) flow diagram (one step method) to prepare Nanofluid. Reproduced from Lo, C.-H., Tsung, T.-T., Lin, H.-M., 2007. Preparation of silver nanofluid by the submerged arc nanoparticle synthesis system (SANSS). *Journal of Alloys and Compounds* 434–435, 659–662.

Table 3 The reported synthesis of nanofluids

Author	Material of nanoparticles	Base fluid	Concentration	Method
Tseng and Lin (2003)	TiO ₂	Water	0.05–0.12 vol. fraction	Two Step
Liu <i>et al.</i> (2005)	MWCNT	EG and engine oil	0.2 to 2 vol%	Two Step

Paul <i>et al.</i> (2012)	Ag	Water	–	One step
Singh <i>et al.</i> (2012)	Al ₂ O ₃	EG and water	0.25–1 vol%	Two step
Fazeli <i>et al.</i> (2012)	SiO ₂	Water	3.5–5 vol%	Two step
Kumaresan and Velraj (2012)	CNT	Water + EG	0.15–0.45 vol%	Two step
Pang <i>et al.</i> (2012)	Al ₂ O ₃ and SiO ₂	Methanol	0.005–0.5 vol%	Two step
Syam Sundar <i>et al.</i> (2012)	Fe ₃ O ₄	Water + EG	0–1 vol%	Two step
(Hung <i>et al.</i> , 2013)	Al ₂ O ₃	Water	0.5–3 vol%	Two step
Selvakumar and Suresh (2012)	CuO	Water	0.1 and 0.2 vol%	Two step
Esmailzadeh <i>et al.</i> (2013)	γ-Al ₂ O ₃	Water	0.5 and 0.1 vol%	Two step
Choudhary and Subudhi (2016)	Al ₂ O ₃	Water	0.1–2 vol%	Two step
Irani (2019)	Graphene Oxide	Water + MDEA	0.1 and 0.2 wt%	Two step
Dalkılıç <i>et al.</i> (2018)	CNT-SiO ₂	Water	0.1–2 vol%	Two step
Ahmed <i>et al.</i> (2018)	TiO ₂	Water	0.1–0.3 vol%	Two step
Anamalai <i>et al.</i> (2018)	Cellulose nanocrystal (CNC)	Water + EG	0.1–1.5 vol%	Two step
Moldoveanu <i>et al.</i> (2018)	Al ₂ O ₃ -SiO ₂	Water	1–3 vol%	Two step

conventional heat transfer fluids to enhance the heat transfer (Das *et al.*, 2008). Investigations using higher thermal conductivity material nanoparticles such as Al₂O₃, CuO, MWCNT, TiO₂, Ag, etc. in conventional heat transfer fluids were ruled. Other thermo-physical properties like viscosity, density, specific heat etc., also plays a vital role to define nanofluid as a heat exchanging fluid. In the area of engine cooling the thermal conductivity and viscosity of nanofluids are very imperative properties to enhance the heat transfer.

Thermal Conductivity

A plethora of literature shows that the thermal conductivity of nanofluids is higher than the base fluid. Researchers focused the use of nanofluids as a cooling fluids in the engine cooling of car radiator. Mohammadi *et al.* (2009) compared the thermal conductivity of γ - Al_2O_3 -engine oil and CuO-engine oil nanofluids and marked that the thermal conductivity increase with the concentration. Compared to base fluid the thermal conductivity of both the nanofluid is enhanced and at 2 vol% concentration γ - Al_2O_3 shown 5% enhancement and CuO shown 8% enhancement. Kole and Dey (2010) reported the enhancement 10.41% at 3.5 vol% concentration of alumina nanoparticles in car engine coolant (HP KOOLGARD). Investigation also reported that the enhancement in thermal conductivity is proportional with concentration and temperature and maximum enhancement reaches 11.25% with 3.5 vol% at 80°C. Vasheghani (2012) dispersed α - Al_2O_3 , γ - Al_2O_3 and AlN nanoparticles at different concentrations separately in engine oil and investigated the thermal conductivity of the prepared nanofluids samples. Increasing tendency of thermal conductivity with concentration for all the cases and at 3 wt% the maximum enhancement recorded 31.47%, 37.49% and 75.23% for engine oil based α - Al_2O_3 , γ - Al_2O_3 and AlN nanofluids respectively. Etefaghi *et al.* (2013) researched with MWCNTs in different concentration in engine oil and stated that it affect the thermal properties of nanofluids. The thermal conductivity of the of nanofluid increased by 13.2% with 0.1 wt% concentration. Elias *et al.* (2014) researched on the thermophysical properties of alumina nanoparticles dispersed in water and EG based car coolant. The thermal conductivity increased with concentration of nanoparticles and temperature, the maximum increment in thermal conductivity was 8.30% for 1 vol% at 50°C. Micali *et al.* (2018) researched on 4-strokes biodiesel engine cooling system based on CuO-water nanofluid. The maximum enhancement in the thermal conductivity was 18% at 4 vol% nanoparticles concentration.

Viscosity

The heat transfer in any fluid flow critically depends upon the viscosity, a minor change in the viscosity affects the convective heat transfer. Furthermore, the nanofluids viscosity depends upon so many factors, the most important factors are nanoparticles concentration and temperature. Einstein Eq. (1) only based upon volume fraction is the theoretical or mathematical expression to find out the viscosity of nanofluid valid only for low concentration (Einstein, 1956). For higher concentration upto 50%, (Kuntiz, 1926) given a correlation Eq. (2).

$$\eta_{nf} = \eta_0(1 + 2.5\phi) \quad (1)$$

$$\eta_{nf} = \eta_0(1 + 0.5\phi)/(1 - \phi)^4 \quad (2)$$

Kole and Dey (2010) dispersed the Al_2O_3 nanoparticles into the car engine coolant (EG based) and found that the nanoparticles concentration enhanced the viscosity. Elias *et al.* (2014) shows the similar trend with Al_2O_3 dispersed in car radiator coolant (EG + Water) and found maximum enhancement was 150% for 1 vol% at 10°C. Mahbubul *et al.* (2013a), Mahbubul *et al.* (2012) and Mahbubul *et al.* (2013b) investigated on the Al_2O_3 -R141b refrigerant and found the similar trend of enhancement in viscosity with the concentration.

Heat Transfer Analysis

As discussed above the conventional fluids have their limitation for convective heat transfer because of their constrained poor thermal properties and for that reason, highly effective sustainable compact technology is necessary to accomplish high heat transfer. The car radiator consists of tubes and fins to circulate fluid and air respectively. Many researcher setups the experimental test rig like shown in Fig. 3 to explore the experimental research. The test rig provides the similar condition of actual vehicle engine.

Experimentally, Kulkarni *et al.* (2008) investigated with aluminum oxide nanofluids as jacket water coolant in diesel electric generator and found that high convective heat transfer coefficient of nanofluids increases the heat exchanger efficiency and the heat transfer coefficient increased with the particle volume concentration. Peyghambarzadeh *et al.* (2011a,b, 2013) focused the research on automobile radiator with Al_2O_3 -water nanofluids and used different variations in concentration. The application of alumina nanofluids enhanced the convective heat transfer upto 45% with low concentration comparison to water. Naraki *et al.* (2013) reported the 8% increment with the CuO-water nanofluid used to investigate overall heat transfer coefficient in laminar flow regime with Reynolds number in between 100 and 1000. Chavan and Pise (2013) used the Al_2O_3 -water nanofluids with low concentration to study the convective heat transfer coefficient. The results show the enhancement of 40%–45% in convective heat transfer efficiency compared to pure water and enhancement increases with flow rate and particles concentrations. Ali *et al.* (2014) researched the on the effects of nanoparticles concentration on the vehicle radiator. The Al_2O_3 -water nanofluid with different concentrations is used and the different parameters are taken into consideration. Results show that the particles concentration upto an optimum level enhanced the heat transfer beyond that heat transfer start deteriorate. The gradual enhancement in heat transfer is upto 1 vol% and after that at 1.5 and 2 vol% the heat transfer deteriorates. Chougule and Sahu (2014) researched on different nanofluids with different concentrations in automobile radiator cooling. Al_2O_3 -water and CNT-water in the range 0.15–1 vol% were prepared and used for cooling performance. The nanofluids exhibit high heat transfer compared to pure water, the maximum enhancement occurred at 1 vol% of 90.76% and 52.03% for CNT-water and Al_2O_3 -water respectively compared to water. Hussein *et al.* (2014a,b) used TiO_2 -water and SiO_2 -water in radiator to augment heat transfer in radiator cooling system. Significant heat transfer enhancement proportional with nanoparticles concentration

Fig. 3 Experimental setup test rig providing similar condition of actual engine.

was observed. Maximum Nusselt number increased 11% and 22.5% for TiO_2 -water and SiO_2 -water nanofluids respectively. To predict Nusselt number the authors developed a mathematical model given in Eqs. (3)–(5) for water, TiO_2 -water and SiO_2 -water nanofluids with 2–4 deviation. Sasank and Naik (2014) used Al_2O_3 -water to investigate effects on the performance of automotive radiator cooling and found maximum heat transfer of 12.4% at 0.1 vol% of nanofluid.

$$\text{Nu} = 1.69414 + 0.325529 \text{ } Q + 0.0058446 \text{ } T \quad (3)$$

$$\text{Nu} = 6.38776 + 0.06018 \text{ } Q - 0.0610291 \text{ } T - 285.668 \text{ } \phi + 0.0176852 \text{ } Q \text{ } T + 51.2556 \text{ } Q \text{ } \phi \quad (4)$$

$$\text{Nu} = -3.0125 - 1.31736 \text{ } Q + 0.083777 \text{ } T - 1071.89 \text{ } \phi \quad (5)$$

Heris *et al.* (2014) used base fluid water + EG (40/60) to suspend CuO nanoparticles in order to study performance of radiator and the maximum enhancement of heat transfer apprehended about 55% compared to base fluid. Hussein *et al.* (2014a,b) investigated with SiO_2 -water nanofluids in the range 1–2.5 vol% concentration and reported that the maximum enhancement in convective heat transfer was about 50%, the friction factor also increased upto 22% compared to water. Satyamkumar *et al.* (2015) used Al_2O_3 -water nanofluids in radiator and found a 26% maximum enhancement at 8 vol% of nanofluid. Sandhya *et al.* (2016) used water + EG (60/40) basefluid with TiO_2 nanoparticles, the experiment conducted in the range between 4000 and 15,000 of Reynolds number. The enhancement upto 37% is apprehended at low concentration of nanofluids. Fig. 4 (a) and (b) shows the results of different researchers between Reynolds and Nusselt number. Higher the Nusselt number higher will be the convective heat transfer. Almost all the researchers find an enhancement proportional with nanoparticles concentrations. M'hamed *et al.* (2016) used MWCNT- water + EG (50/50) nanofluid in car engine system (Proton Kelisa 1000cc) radiator to study heat transfer performance. The heat transfer enhancement was proportional to volume concentration of nanoparticles and for 0.5 vol% almost 200% enhancement is reported. Goudarzi and Jamali (2017) used inserts in the tube of radiator with EG based Al_2O_3 nanofluids and reported the heat transfer enhancement and stated that the thermal performance of the system with inserts is more than 1 which means that this technique can be used into the radiator for research in order to enhance the heat transfer. Selvam *et al.* (2017) studied the performance of radiator with graphene- water + EG nanofluid, the convective heat transfer apprehended start from 20% and upto 51%. However, the pressure drop also increased while increasing concentration. Lately, Subhedar *et al.* (2018) reported the reduction in frontal area if base fluid replaced by nanofluid. The research was focused on the heat transfer in car radiator by Al_2O_3 -water + Mono EG (50/50) nanofluid as a coolant. The Nusselt number changes from 3.89% to 28.47% as the particle concentration change from 0.2% to 0.8%. Almost 30% rise noted with the low vol% concentration of nanoparticles compared to base fluids. Ahmed *et al.* (2018) researched on the radiator performance with TiO_2 -water nanofluid with 0.1, 0.2, and 0.3 vol% in laminar range between 560 and 1650 of Reynolds number. The significant enhancement with 0.2 vol% is captured almost 47% compared to water.

Numerically, Tijani and Sudirman (2018) studied the performance of Al_2O_3 and CuO – water + EG (50/50) nanofluid as a coolant of car radiator with heat transfer models simulated using ANSYS fluent solver. The CuO based nanofluid at higher concentration apprehended more heat transfer compared Al_2O_3 and base fluid. Mutuku (2016) studied the heat transfer performance of nanofluids as a coolant in radiator, CuO , Al_2O_3 and TiO_2 nanoparticles dispersed into EG. The similarity approach

Fig. 4 Experimental heat transfer analysis of (a) at higher Reynolds number (b) at low Reynolds number.

using Runge–Kutta–Fehlberg method used. [Leong et al. \(2010\)](#) studied the performance of automobile radiator with nanofluid as a coolant. Different data and empirical correlation are used to investigate heat transfer performance mathematically and reported that heat transfer rate enhance with concentration. Reduction in frontal area about 19% with optimum parameters.

Challenges, Application and Future of Nanofluids

Recent researches on the nanofluids as an engine coolant are summarized in this article. The challenges that are facing by nanofluid industrial application are reviewed from the literature. Firstly, both the techniques used to prepare nanofluids are facing problems and that should be addressed for large scale cost effective production. More experimental and simulation work needs to be done to know the mechanism for stable nanofluids. Though two step method of preparation of nanofluids is mostly used and it is cost effective and can be used for large scale production but researchers still facing the stability problems with this technique. The main disadvantage with one step method of preparation is the high cost of synthesis. The other important factor needs to be addressed is the no chemical and corrosion effects on the heat transfer system. Better and longer stability of nanofluids will be the

indispensable milestone in the evolution of nanofluids as a coolant. The mechanism behind the enhancement of thermal conductivity is still indistinct, also the precise reliable theoretical model to predict thermal conductivity is unavailable. More experimental work is required to know the phenomena behind the enhancement in thermal conductivity and to develop a reliable general theoretical model to predict thermal conductivity. Moreover, the results of researchers are not consistent for different thermophysical properties. Another significant factor is increment in the viscosity which leads to requirement of additional power to pump high viscous nanofluids. Selection of optimum parameter such as shape, size, concentration of nanoparticles could be used to produce a coherent nanofluid with high thermal conductivity and less viscosity. The other vital opinion to increase the potential application of nanofluids is that no major changes only minor changes have to be in the cooling system.

Apart from application in car radiator cooling, the nanofluids can be applicable to engine lubrication. The application field of nanofluid is very wide like electronics cooling, medicine, space, nuclear, defence, biomedical, solar etc. Kim *et al.* (2007a,b) studied the feasibility of nanofluids in nuclear applications (Buongiorno *et al.*, 2009). In medical field the nanofluids are used with significant results in so many cancers related diseases (Scherer and Neto, 2005; Raj and Moskowitz, 1990). There are so many fields in which nanofluids can directly be applicable, researchers are working to make the nanofluids more consistent to make it commercial (Wong and Leon, 2010).

Moreover, nanofluids can be inevitably applicable to almost every field of heat energy exchanging system in the future. The industrial large scale cost effective production with better and longer stability of nanofluids will bring the revolution in the heat exchanging system field.

Outlook

The automobile engine cooling system and the coolants are summarized in this article. The different methods to synthesize nanofluids are discussed thoroughly. Thermal conductivity and viscosity are the key parameters of nanofluids potential in car radiator cooling. Effect of fundamental parameters on these key properties is discussed and compared. The performance of automobile car radiator experimentally and numerically studied by researchers are compared. The convective heat transfer in the radiator is compared of different researchers for different nanofluids. The Nusselt number and Reynolds number at various concentration for different material nanofluids car radiator are summarized. The challenges for the nanofluids in the radiator or car engine cooling is reported along with different application field and future scope of the nanofluid.

An Assessment of Hydrogen Energy Utilization for Sustainable Development

Ahmet Z Sahin, King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia

© 2020 Elsevier Inc. All rights reserved.

Introduction

Production and conversion technologies for hydrogen have been developed and well documented. It is proven that the utilization of hydrogen as a fuel has superior advantages over that of the other forms of fuels. Despite of all these advantages, hydrogen has not been extensively used in an industrial scale except in the outer space for space programs. Technical, social, economic and political aspects all contribute to the limited use of the hydrogen in a large scale. On the other hand, there is a growing awareness on the environmental damage and health consequences in using the fossil fuels. Thus, it has become inevitable to replace the conventional fossil fuel-based technologies with cleaner alternatives. Hydrogen based economy is a promising alternative.

When considering the environmental impact such as harmful emissions and waste of resources the energy efficiency is found to be the most important aspect. Therefore, it is desirable to improve the energy efficiency and the performance of any process to reduce the environmental consequences. Once the energy efficiency is improved, the harmful emissions and waste of resources will be reduced. The economic aspects of such processes will also improve.

Commercial use of hydrogen includes variety of processes such as ammonia production, hydrogenation of oils and fats, production of methanol, production of hydrochloric acid, and reduction of metallic ore. Hydrogen is also used in its liquid form as a cryogenic substance and for superconductivity. A major portion of the commercial hydrogen (nearly two-thirds) is used for ammonia production. Other uses of hydrogen include chemical processes such as hydrocracking, hydrodealkylation, and hydrodesulphurization. Hydrogen is also used as a fuel to a lesser extend for power and electricity production, and for heating purposes in buildings.

Since hydrogen is a clean source of energy without any harmful products during its use as a fuel it can help in preserving the healthy environment by reducing and/or eliminating the hazardous emissions that occur during the conventional fossil fuel consumption.

As the awareness on the environmental consequences of using non-renewable fossil fuels is increased, hydrogen-based economy has become one of the attractive options. However, hydrogen is not freely available in the earth in large quantities and therefore it is not a source of energy. Currently, it is produced through burning the fossil fuels such as natural gas, coal and oil. Thus, the production of hydrogen through these conventional methods lead to serious environmental problems. The clean option for producing the hydrogen remains to be its production through the renewable energy sources. As the renewable energy sources such as solar and wind are intermittent in nature, the hydrogen produced by the renewable energy sources is considered to be an energy carrier. This means that, the long term and wide spectrum of hydrogen-based economy and electricity production must be based on the hydrogen that is originated from the renewable energy sources.

Hydrogen-based economy is a very attractive option especially for the developing countries that do not have large amount of fossil fuel reserves and the required infrastructure but possess considerable amount of renewable energy. Stand-alone applications of the renewable energy sources make it more attractive for the under-developed countries and the remote localities where the national electrical grid is not available. The hydrogen generated through the renewable energy systems, then, may be converted to power through the fuel-cell power systems. Although the initial cost of such fuel-cell systems may be high, in the long run, they will be profitable from the economic and environmental point of view (Veziroglu and Barbir, 1992).

When hydrogen-based economy is considered, the entire system needs to be evaluated through the technologies used for the production, storage, transportation, distribution, and utilization of hydrogen.

Why Hydrogen Energy?

Depletion of Fossil Fuels

Currently two-thirds of the world energy demand is met by the fluid fossil fuels such as oil and natural gas. This is because these fuels provide convenience and are readily available as they can be easily transported and stored. Coal also have a significant share in world energy supply. However, these non-renewable energy reserves of are expected to become non-feasible as they are being depleted. The production of fossil fuels is estimated to decrease after a peak is reached. On the other hand, the world energy demand is expected to increase in a continuous manner, as a result of increase in the population and the need for improving the living standards that would require more energy consumption per capita.

The total world population was estimated to be 7.7 billion in 2018 and is expected to reach about ten to twelve billion by the end of the 21st century. The energy demand is estimated to double by the end of the century. Therefore, there will be a growing gap between the demand and the production of fossil-fuels that are not renewable. This will lead to increase in the prices of fossil fuels during the coming several decades. This motivates the development of technologies for the non-fossil and renewable energy alternatives such as solar, wind, geothermal, biomass, and the development of hydrogen-based economy that is based on such renewable alternatives.

Damage to the Environment

It is well known that the technologies used for extraction, storage, transportation, processing and utilization (i.e., combustion) of fossil fuels lead to serious environmental damage and result in negative impact on the economy and the society (Barbir *et al.*, 1990).

The harmful emission through the combustion of fossil fuels cause air pollution that is a source of damage for the human health, animals, plants, and buildings. In turn, the air pollution leads to global warming and reduced visibility. The pollutants that are emitted to the atmosphere form acid rain in the form of sulfuric and nitric acids after chemically reacting with water and other atmospheric compounds with the aid of the sunlight. These acids that are produced may also appear in the form acid dew, acid fog, and acid snow. The harmful pollutants may turn into secondary pollutants too such as ozone, aerosols, and peroxyacyl nitrates.

Carbonic acid is produced by carbon dioxide in equilibrium with water. Deposition of this carbonic acid in wet or dry from causes damage for the terrestrial ecosystem. It causes soil and water acidification which affect the life on the earth through adverse consequences in humans, animals, plants and buildings. Carbon dioxide and other combustion (greenhouse) gases such as methane, nitrogen oxides and chloro-fluorocarbons lead to warming of the atmosphere. This occurs as a result of increased absorption of the infrared radiation emitted by the earth into the atmosphere and the solar irradiation causing global warming. As the atmospheric temperature rises the ice cap around the poles melt causing serious climate changes and rise of the sea level. This in turn, results in natural disasters such as floods and storms in some areas and droughts, heat waves and wildfires in the other.

Properties of Hydrogen

Hydrogen is the smallest element. Its molecular mass is 2.016. It has no color and odor. The density of hydrogen is 0.08376 kg/m^3 that is roughly 14 times less than the air at the standard atmospheric temperature and pressure. The heating value of the hydrogen is two to three times higher than that of other fuels. Combustion of hydrogen is possible over a wide range of gas concentrations. As the hydrogen is burned it produces only water causing no harm to the environment. Therefore, hydrogen is a clean and harmless fuel if it is produced using the renewable energy sources. It can be produced by breaking apart the water molecule and separating the hydrogen in a so-called electrolysis process using electricity. When it is re-combined with oxygen in the air electricity or heat can be produced. As the hydrogen is burned, the combustion products contain only water and no polluting agents such as particulate, carbon dioxide, or carbon monoxide are produced.

Challenges in Using Hydrogen

Despite of all the above-mentioned superior properties of hydrogen, it is not yet widely used in a large scale for industrial applications. Various unresolved political, economic and social issues hinder the development of hydrogen economy. Lack of consensus on the energy priorities, the public perception in relation to the safety of hydrogen energy and the economic aspects of hydrogen energy production, storage and transportation all contribute in restricting the widespread use of hydrogen energy. On the other hand, there are other supporting aspects for the hydrogen economy development. Dependence on the foreign energy supply is a primary concern for national security. The environmental degradation in using fossil fuels and the increasing demand for the energy are some of the supporting aspects in the development of the hydrogen-based economy.

Apart from the political, economic and social issues there are yet significant challenges in relation the scientific and technical aspects in promoting the hydrogen economy. These challenges refer to the production, storage, transportation and use of hydrogen. Once the scientific and technical challenges on the production, storage, transportation and use are resolved the required infrastructure need to be built or part of the existing energy infrastructure may be modified and used for the smooth transition to hydrogen economy. The infrastructure needed should accommodate all the technical steps from the production to the consumption of hydrogen. For the hydrogen economy to become a reality, it should also be demonstrated that hydrogen as the energy carrier is competitive in terms of unit cost of energy.

Hydrogen Production Technologies

Hydrogen From Fossil Fuels

Currently, most of the industrial hydrogen is produced from the natural gas through the steam reforming process. Coal and biomass are also used for hydrogen production, but these resources produce larger amounts of CO_2 . Steam reforming of these resources is also complicated because they contain water, sulfur, nitrogen and nonvolatile minerals.

Hydrogen that is produced from the fossil fuels is mostly used in the agricultural (to produce fertilizer), petroleum and chemical industries. It is also used for transportation and food industries. Therefore, it is important to establish safe and cost-effective methods for treating and storing the generated CO_2 in reforming the fossil fuels. In relation to safe storage of the produced carbon dioxide various technologies are proposed. These include injection into deep ocean, depleted oil wells and saline reservoirs (Kim and Edmonds, 2000). The non-purity of hydrogen produced by the steam reforming of fossil fuels poses another

challenge and drawback in direct utilization of hydrogen for the fuel cells and for the transportation sector. The purification process requires costly purification systems.

Hydrogen From Solar Energy

Solar energy is the most promising source of clean energy for producing hydrogen. Hydrogen can be produced using solar energy through electrolysis of water with solar cells, photocatalytic and photobiological processes in which water is split into hydrogen and oxygen, and through solar thermal process. The advantages of producing hydrogen through these processes using solar energy include its purity and suitability for use in low temperature fuel cell applications and for automobiles. There are many applications of solar hydrogen. However, the main drawback for the wide-spread use of solar hydrogen is the cost of solar cells and their efficiency. The current efficiency of solar photovoltaic cells varies between 3% and 25%. For the solar hydrogen to be a widespread and feasible option, the cost of solar cells and particularly their efficiencies need to be improved. Then, the solar hydrogen with its high purity will promote the wide-spread implementation of fuel cells by eliminating the expensive purification systems.

Hydrogen From Biological Systems

Hydrogen is the most common element in biological systems. Most commonly used method of hydrogen production from the biological systems is the anaerobic fermentation (Etiope and Klusman, 2002). Renewable and clean hydrogen can be produced by gasification, anaerobic digestion and cellulosic ethanol processes. The biomass gasifier produces carbon monoxide, carbon dioxide, methane and hydrogen. The anaerobic digesters primarily produce methane by which hydrogen is produced using steam reforming process. During the cellulosic ethanol production hydrogen can also be produced through a thermochemical process. There are significant efforts directed to understanding the type of organisms and the biochemical processes that are responsible for efficient production of biological hydrogen (Reysenbach and Shock, 2002). These processes can be improved considerably and optimized for large scale cost-effective hydrogen production.

Hydrogen production from the biological systems occurs naturally in a substantial amount. However, this process takes place in highly distributed fashion and in low density. Large quantities and concentrated form of biological hydrogen production would be needed for the industrial applications of such resources. Yet the efficiency of biological hydrogen production through living microorganisms is relatively low as compared with that of solar photovoltaic electrolysis process. Cost competitive biomass-based hydrogen can be produced as a result of maturing of the biomass gasification technology and reduction in the feedstock costs.

Hydrogen Production by Thermal Energy

Thermal energy can also be used directly to split water into hydrogen and oxygen without a need for the electrical energy and electrolysis process. In this case, the process is named thermo-chemical water-splitting for which the thermal energy or heat required is obtained through concentrated solar energy, burning fossil fuels or nuclear reactions. The temperature needed for such process is in the order of 500°C which can easily be obtained by concentrated solar power. There are several proposed thermo-chemical cycles available in the literature for producing hydrogen from the thermal energy using high temperature reactors (Brown *et al.*, 2002). Among these cycles; the calcium bromide-iron oxide cycle, the Westinghouse cycle, and the sulfuric acid-hydrogen iodine cycle are the most promising ones. In such cycles, corrosion and high temperature failure of materials are the challenges to overcome. Finding suitable materials for enduring such aggressive chemical environment is the main barrier for the development of this technology.

Safety Hazards in Hydrogen Use

For the public reception of the hydrogen economy there are two main issues. These relate to the safety and the environmental concerns. Safety is perhaps the most important concern when it comes to adopting the fuel in an industrial scale. Safety hazards of hydrogen exposure for the human health needs to be assessed in a detail manner. Long term exposure in particular may be harmful for the health. Safety and environmental concerns are directly associated with the social and technical challenges that need to be considered and resolved for the viability and success of hydrogen economy. The safety hazards in relation to use of hydrogen can be classified into three main types; they are either *physiological* (frostbite, respiratory ailment, and asphyxiation), *physical* (phase changes, component failures, and embrittlement), or *chemical* (ignition and burning) (NASA, 1997).

Physiological Hazards

Due to the small size of hydrogen molecule, it has higher tendency and ability for leakage as compared with other gases. On the other hand it can be ignited in a wide range of concentrations. Therefore, hazards in relation leakages, fires, explosions may occur. These will lead to injury of the people and toxicity of the surrounding. Leakage of hydrogen gas in the air may lead to dilution of the oxygen which in turn may cause asphyxiation especially in closed spaces. Explosion of hydrogen gas may also cause injury for

the people around as it may result in pressure waves. As the flame originating from the hydrogen burning is invisible it may affect people by radiant heat from the hydrogen flame. The level of the injury in this case depends on many factors such as the time of exposure, rate of burning, heat of combustion, size of burning area, and the humidity of air in the surrounding. Contact with the cryogenic liquid hydrogen may cause cryogenic burning. Exposure with the large amount of cryogenic liquid hydrogen could result in hypothermia unless proper precautions are taken.

Physical Hazards

Due to its smaller size, hydrogen's ability to leak through holes and joints at low pressure is 1.26–2.8 times faster than that of natural gas (Larminie and Dicks, 2003). Therefore it requires more careful sealing when stored in vessels and transported through the fuel lines. Another serious aspect of the hydrogen use is that long term exposure of hydrogen gas causes hydrogen embrittlement for the metallic and non-metallic materials in contact with it. This will degrade the mechanical properties of the storage containers, pipe lines and the seals.

The range of flammability (ignition range) of hydrogen and air mixture varies from 4% to 75% on volume basis as shown in Fig. 1. This range is considerably larger than that of methane and gasoline. The ranges of flammability for natural gas, propane, and gasoline are 5.3%–15%, 2.1%–10%, and 1%–7.8%, respectively. Lower limit of ignition of hydrogen is slightly less than that of methane but higher than gasoline and propane (Larminie and Dicks, 2003; Ogden, 2002).

The energy required for the ignition for hydrogen as well as methane and gasoline is shown in Fig. 2. It needs very low energy (0.02 mJ) for igniting hydrogen. The other two fuels, namely methane and gasoline, require about ten times higher energy for the ignition. This shows how easy it is for the hydrogen to catch fire. The flame speed of hydrogen is roughly 7 times larger than that of the natural gas or gasoline. Therefore, detonation and deflagration may occur much easier during the hydrogen combustion. On the other hand, the detonation in case of hydrogen combustion may start at 13%–18% hydrogen/air mixture which is 2 and 12 times higher than that of natural gas and gasoline, respectively. In addition, the explosive energy during the explosion of hydrogen

Fig. 1 Flammability ranges of three gaseous fuels in air.

Fig. 2 Comparison of ignition energies of three gaseous fuels in air.

gas is 22 times less than that of gasoline vapor for the same volume of fuel. However, dangerous explosion may occur when hydrogen leaks through a relief valve. As the flame of hydrogen is invisible, people may not be aware of the flame and the existence of fire when it occurs.

Chemical Hazards

Oxygen depletion is one of the serious consequences in burning hydrogen. As the combustion process takes place oxygen is permanently removed from the atmosphere (Santilli, 2000). This happens when the hydrogen that is generated using fossil fuels reacts with oxygen in the air. The solution for this problem would be to use renewable energy such as solar power for producing the hydrogen fuel via electrolysis process. However, this process is costly and has low efficiency.

Density of hydrogen is very low. Therefore, it does not have sufficient energy density and is not suitable in its compressed form for use in vehicles. Therefore, it needs to be carried in the liquid form. This causes additional cost and complication during the transportation, storage, distribution and use.

Hydrogen in its gas form must be kept confined in storage tanks and transportation lines so that no leak occurs. It is essential to study the consequences of leak in large quantities in case it occurs especially in closed spaces.

Hydrogen gas has its own characteristic features different from the conventional fuels. Its ability to embrittle the materials that it is in contact with for long duration, its very low density and therefore its high buoyancy, its easily leaking and fast diffusion behavior, and its combustion characteristics are all very different from the other common fuels. As the hydrogen economy is promoted further research needs to be carried out to explore the hazards in dealing with hydrogen. At the same time, considerable efforts are needed for educating people on the consequences of hydrogen use and required training should be provided to the personnel that will handle hydrogen in various fields of hydrogen economy.

Storage of Hydrogen

Hydrogen is stored either in gaseous form, or liquid form, or in metal hydrides. There are challenges in each of this type of storage technologies. Due to its low density and low boiling point, a reasonable amount of hydrogen fuel for driving a vehicle will require a very large size of tank. In automotive industry, hydrogen tanks containing gaseous hydrogen at a pressure of up to 800 bar are being used. The advantage of storing hydrogen in gaseous form under high pressure is that it does not require additional energy to extract the hydrogen from the storage medium. However, filling the fuel tank with high pressure is rather costly since this requires powerful compressors. Other methods of storing large quantities of hydrogen gas include underground caverns, salt domes, and depleted oil/gas fields.

Cryogenic hydrogen in the liquid form provides high energy density. Liquid hydrogen is usually stored in metal storage tanks. It can also be stored in organic liquids. The main advantage of storing hydrogen in the liquid form is that it provides high energy density without requiring high pressures. However, the main disadvantage of liquid hydrogen storage is that it is a very costly process to liquefy hydrogen. In addition is required to provide good insulation. Otherwise, the evaporated liquid hydrogen as a result of heat leak to the cryogenic hydrogen needs to be vented in order to prevent over-pressurization of the storage tank. This constitutes significant losses of hydrogen.

Hydrogen can also be conveniently stored in certain materials by adsorption, absorption, and chemical reaction. For the case of adsorption, hydrogen in its molecular form is attached to the surface of solid materials that are kept at low temperatures and high pressures. Hydrogen is extracted by reducing the pressure and increasing the temperature. This method requires highly porous materials with high surface area. In this respect, zeolites, metal oxides, carbon nanotubes and graphene are some of the popular choices as adsorption materials. Since high pressure is not needed, this method is a relatively safe method of hydrogen storage. For the case of absorption, hydrogen is absorbed in the bulk of material that is named metal hydrides. Metal hydrides can provide large storing capacity of hydrogen and are resistant to damage. The main disadvantage in using metal hydrides is that refueling of hydrogen may take longer. In this regards, light weight metals such as Li, Mg, Al and Na are being investigated in order to reduce the weight of the metal hydride storage system. In chemical hydrogen storage method, chemical reactions are used to generate and use hydrogen. In this regard, chemical hydrides are reacted with water and alcohol to produce hydrogen.

Transportation of Hydrogen

Transportation of hydrogen is done currently in three major methods; pipelines, high-pressure trailers, and liquified hydrogen tankers. Transportation of hydrogen through pipeline requires expensive infrastructure, however, the operation cost will be low. Hydrogen embrittlement is an important issue and therefore the current pipeline can not be used for this purpose. High pressure trailers are more convenient for transporting pressurized hydrogen gas, however, the cost is higher. This mode of transportation is especially suitable for small market needs because the capacity of the trailer is limited. Liquified hydrogen tankers are more convenient for transporting hydrogen in longer distances using trucks, railway, and ship. The major problem in this kind of transportation is the insulation to minimize the heat transfer and therefore the

evaporation losses. This mode of transportation is the most common and preferred method and offers the cheapest among all the options of transportation.

Hydrogen Energy Conversion Methods

There are mainly two methods of energy conversion using hydrogen. As a fuel, hydrogen can be used in internal combustion engines and in fuel cells. Hydrogen can be used in the existing internal combustion engines with small modification. The required modifications are due to the different properties of hydrogen as compared with those in other fossil fuels. These properties are the required low ignition energy, the flammability range, flame speed, autoignition temperature, diffusivity rate and the density. The most important advantage of hydrogen over the other common fuels is that hydrogen combustion does not produce any environmental pollution. On the other hand, hydrogen is directly converted to electricity in fuel cells through electrochemical process. The most fuel cells are proton exchange membrane and solid oxide fuel cells.

Conclusions

Use of hydrogen as an energy carrier in a wide spread hydrogen economy was discussed. The challenges and the safety issues that need to be addressed were presented. The socio-economic aspects of hydrogen energy use were analyzed. It is shown that hydrogen economy has superior advantages over the current fossil-based economy in terms of environmental impact and sustainability. However, there are still important scientific and technical challenges to overcome before the hydrogen economy to become a reality. Many of these challenges can be overcome through the recent advances in renewable energy with the help of materials science, physics, biology, chemistry, and nano-science. The superior properties of hydrogen over the conventional fossil fuels offer motivation and promise for implementation of the hydrogen economy. The concerns related to the safety hazards for the people, equipment and the environment have been presented by considering the phases of production, storage, transportation, and end usage.

Bacterial Cellulose Based Nanocomposites for Electronic and Energy Applications

Sreeja K Sathish and Satish Vitta, Indian Institute of Technology Bombay, Mumbai, India

© 2020 Elsevier Inc. All rights reserved.

Cellulose is a naturally occurring biopolymer produced by both plants and certain types of bacteria. Cellulose has a highly developed hierarchical structure made of the basic block or monomer $[C_6H_{12}O_6]$ which is nothing but a simple sugar molecule. This saccharide molecule undergoes polymerization to a long chain polysaccharide which forms the backbone of the macroscopic cellulose fiber. The number of monomers in this long chain polymer vary depending on the source, plant or bacteria, and also on the synthesis technique, up to $\sim 15,000$ units. The alternate chains are rotated by 180° in order to overcome the steric hindrances so as to achieve a dense packing of chains. These bundles of chains are known as microfibrils with a typical diameter of about 3–4 nm and the crystallographic unit in these microfibrils has typical unit cell size of $0.8 \text{ nm} \times 0.8 \text{ nm} \times 1.0 \text{ nm}$. This means the microfibril has a width of 3–4 unit cells. It should be noted here that cellulose exists in many polymorphic forms – Cellulose I to IV depending on the treatment given to the natural cellulose which is Cellulose I. The microfibrils in turn are aligned and bundled into aggregates known as macrofibrils which can range in diameter/width from 10 to 30 nm and can extend in length up to several microns. The essential differences between plant and bacterial cellulose are:

- Average degree of polymerization in plant cellulose is typically lower compared to bacterial cellulose and as a result, the microfibril length is reduced.
- Plant cellulose invariably exists together with hemicellulose and lignin which are amorphous polysaccharides with short chain length. Bacterial cellulose, on the other hand, is pure form and hence has better mechanical strength compared to plant cellulose.
- The extent of crystallinity in the microfibrils is far higher compared to that of plant derived cellulose.

Bacterial cellulose (BC) with its high purity, crystallinity and hence mechanical strength is considered to be an excellent choice to be functionalized for a variety of applications ranging from simple speaker diaphragm to active electronics. The added advantage of this material is that it is biocompatible together with being biodegradable. Hence some of the most recent applications of BC for the electronics and energy sector are discussed below. These applications are by no means exhaustive in collection and are only intended to highlight the role of BC. Before discussing these applications, the biochemical synthesis mechanism and commercial production methodologies are discussed in brief as it is non-trivial to synthesize large quantities of good quality BC.

Biochemical Synthesis Mechanism

Microbial cellulose is produced naturally by a variety of microorganisms such as bacteria, and algae. Gram-negative bacteria such as *Acetobacter*, *Agrobacterium*, *Azotobacter*, *Rhizobium*, *Pseudomonas*, *Salmonella*, *Alcaligenes*, and Gram-positive bacteria such as *Sarcina ventriculi* are capable of producing cellulose. However, the most widely studied bacterial genera belong to three major groups namely, *Acetobacter xylinum*, *Acetobacter hanseii*, and *Acetobacter pasteurianus*. Amongst these, *Gluconacetobacter xylinum* (now renamed as *Komagataeibacter xylinus*) has been extensively used for the synthesis of cellulose at a laboratory scale as the cellulose yield obtained is quite high in terms of quantity and quality, which also justifies the growing commercial interest. The exact biological function of cellulose, synthesized extracellularly by different prokaryotes such as bacteria and algae is still not completely known. It is widely believed that these microbes, especially the bacteria, produce cellulose in order to protect themselves from extreme conditions in the environment (heat, UV radiation, etc.). It is also speculated that the low density of cellulose allows the bacteria to remain anchored to them at the interface of the culture medium and air (in static reactor models), thereby providing ambient conditions for optimal growth through cell division (Vitta and Thiruvengadam, 2012).

Nevertheless, the biochemical processes that lead to the formation of cellulose and the synthesis pathway are very well understood in the bacterium *Gluconacetobacter xylinum*. The synthesis proceeds via two main steps:

- The first step consists of the formation of uridine diphosphoglucose (UDPG) from carbon precursors by phosphorylation reaction (which maybe sugars such as glucose or fructose, or other compounds such as pyruvates, di-carboxylic acids, etc).
- The second step involves the polymerization of glucose into long and unbranched chains of cellulose through β -1,4-glycosidic linkages.

In the first step, glucose and fructose (which are present together in the culture medium) get converted to Glucose-6-phosphate through some enzyme-mediated reaction steps involving glucokinase, phosphoglucumutase, etc as biocatalysts. The Glucose-6-Phosphate thus obtained, forms the basis for the production of uridine diphosphoglucose (UDPG) in the presence of UDP-glucose pyrophosphorylase. Phosphorylation of glucose is the most important step in this process as the UDPG serves as the substrate for the enzyme cellulose synthase, in the second step. The complex enzymatic machinery with one end bound to UDPG in the cytoplasm and the other end extending outward from the phospholipid bilayer outer membrane performs the essential task

of synthesizing cellulose by polymerizing approximately 200,000 glucose units per second (Ross *et al.*, 1991). Cellulose synthase is assisted by accessory proteins present in the cytoplasmic membrane and the cellulose produced, extends outwards through pores present on the cell surface, each orifice measuring ~ 10 nm in diameter. Through the pores, sub-elementary fibrils of 1.5 nm of cellulose emerge and aggregate together to form a microfibril. Several bundles of microfibrils extend three-dimensionally to create the highly porous network of microbial cellulose. The packets of microfibrils are highly directional in their orientation, and these are associated with high crystallinity which is observed in BC.

In addition to the high degree of crystallinity (about 71%), BC is exceptionally pure (99% water and 1% cellulose in hydrogel form) and possesses good tensile strength (Young's Modulus of 33.3 GPa). Moreover, it is chemically inert, highly flexible, biocompatible and biodegradable. Due to its superior properties, efforts have been made to scale up the production of microbial cellulose, and some pilot plants have been set up.

Production of Bacterial Cellulose

Bacterial cellulose utilization on a commercial scale requires the production of BC in large quantities, and the prospects in this regard are quite challenging. This section aims to provide a brief overview of the various traditional and industrial methods of BC cultivation and the latest developments in this field.

The most common method of laboratory synthesis of microbial cellulose involves acetic acid bacteria of the genus *Gluconacetobacter*. Static and dynamic culturing methods have been used for growing cellulose. In the static mode, the bacterial culture is kept undisturbed in a shallow tray for several days till a smooth, continuous pellicle growth of cellulose is observed. The dynamic method includes airlift reactors, shaker flasks, rotary reactors, and agitated cultures. While the static reactors yield thin sheets of bacterial cellulose of homogenous thickness, those obtained by dynamic methods are in the form of lumps and globules (Wu and Li, 2015).

Production of BC in the static reactor method depends on the surface area and the availability of air for the cellulose growth. The bacteria responsible for the production of cellulose are often found anchored to the growing cellulose sheet, and the growth of cellulose ceases as soon as oxygen supply gets interrupted at the interface of culture medium. However, at present, BC is cultivated for commercial applications from Nata De Coco by the fermentation process and is often termed as 'biocellulose' (National Research Council (U.S.), 1992). Biocellulose is produced in large quantities in the form of 'bacterial cellulose fleece' which are obtained from large plastic containers under static conditions. Biocellulose thus obtained is suitable for food and cosmetic industries but cannot be used for other applications in medical, pharmaceutical, electronic and energy devices as it requires BC grown under uniform culture and growth conditions with exceptional purity and material stability. Furthermore, BC production using conventional static reactors cannot be scaled up for commercial applications due to the slow growth rate of microbes and the limitation in oxygen supply at the interface of the cellulose. Therefore, taking economic factors into consideration, horizontal lift reactors, rotating disc reactors and bubble columns are preferred for the growth of cellulose in bulk quantities for industrial applications (Krystynowicz *et al.*, 2002).

In a rotating disc reactor, the bacteria responsible for the growth of cellulose are attached to the rotating disc such that they alternate in contact with the culture media and oxygen during the course of rotation. The production of BC in these reactors is influenced by factors such as the ratio of surface area to volume of the media and rotational speed. The advantages of this process are ample supply of oxygen and lack of shear stresses in the solution which serves to promote the growth of bacteria thereby increasing the output of cellulose. Optimal production of BC was achieved by Krystynowicz *et al.* (2002) with a rotational speed of 4 rpm and a surface area to medium volume ratio of 0.71 cm^{-1} .

Jung *et al.* (2005) developed and investigated a novel system equipped with a turbine impeller and a spin filter for the production of BC. The entire system comprising of the impeller with six blades and a spin filter, is encased in a stainless steel cylinder, attached to an agitator shaft. The maximum yield of BC was 4.57 g/L after 140 h of culture using *Gluconacetobacter Hanseii*, maintained at an acidic pH of 5.0 at ambient temperature. This reactor is a static reactor where BC pellicles form on both the surface of an oxygen-permeable synthetic membrane and on a liquid surface. Also, thin sheets of bacterial cellulose have been obtained by the use of support structures such as silicone rubber, porous membranes, polymer composite materials and agar (Islam *et al.*, 2017). However, the yield is still considered quite low for pilot-scale production of BC.

The latest addition to the list of bioreactors for the production of BC is the Horizontal Lift Reactor or HoLiR which is a novel bioreactor that combines the benefits of both static and agitated cellulose growth methods. The approach was first demonstrated by Kralisch *et al.* (2009) by using a 180 L bioreactor. HoLiR allows for steady-state yet semi-continuous cultivation and harvesting of BC fleeces in planar form. The method has been adopted and successfully scaled up by JeNaCell, the German company that leads the production of high-quality BC-based products for cosmetics and dermatological applications. Other pioneers in the field include BOWIL Biotech in Poland, S2Medical in Sweden, fzmb in Germany and DePuy Synthes in Pennsylvania, USA, who are engaged in the development of therapeutic and cosmetic products based on BC (Klemm *et al.*, 2018).

The up-scaling of HoLiR by JeNaCell has paved the way for mass production of high-quality BC which could open up new avenues for sophisticated applications in the electronics and energy sectors apart from the medical industry. However, it is believed that detailed studies on the biochemical pathways, media used for cultivation of BC and its control variables, as well as the design parameters for bioreactors could improve the production efficiency of BC even further.

Electronic Devices

Electronic appliances, in general, are posing a serious threat to environment, specifically with respect to mounting quantities of waste. Among the several items that comprise electronic appliances, computers and mobile phones contribute the maximum to mounting waste because of their relatively short life span compared to appliances such as washing machines, air conditioners and so on. This electronic waste contains both metals and polymers which can cause significant environmental damage and thus detrimental effects to human health, if not properly handled and recycled. Hence it becomes imperative to develop highly efficient handling and recycling technologies to mitigate environmental damage. A better alternative, however, would be to develop new environmentally compatible and sustainable materials that will deliver the same functionalities. In this context, cellulose becomes a highly attractive material due to its environmental suitability and sustainable nature coupled with its mechanical strength. Functionalizing this material for various applications ranging from imparting simple electrical conductivity to different actuators can lead to better environmentally friendly devices. A few of such most recent efforts in developing BC based nanocomposites are discussed below.

Bacterial cellulose with its fibrous structure exhibits extremely good mechanical strength and a dielectric behavior due to the polar arrangement of saccharide molecular chains. Apart from these two inherent properties, cellulose does not have any other property which can result in functionality to cellulose. Hence in order to induce other functionalities, suitable secondary phase materials have to be incorporated. To induce dual functionalities of electrical conduction and magnetic response, Thiruvengadam and Vitta incorporated nanoparticles of Ni in one case and permalloy in the other into freeze dried BC by aqueous state reduction of precursors (Thiruvengadam and Vitta, 2017a,b). The conductivity of Ni particles incorporated in the BC was found to increase by 7 orders of magnitude for a loading of 20 vol% of nanoparticles. This composite paper had a magnetic energy product of $\sim 60 \text{ J m}^{-3}$, Fig. 1(a) and (b). The permalloy incorporated bacterial cellulose xerogel also exhibits soft magnetic behavior as well as electrical conductivity, Fig. 2(a) and (b). The presence of electrical conductivity as well as magnetic sensitivity even in the hydrated state of the nanoparticle composite clearly shows that the nanoparticles are firmly attached to the cellulose fiber surfaces and not loosely held in its porous structure. This work clearly demonstrates that multiple functionalities can indeed be induced in bacterial cellulose. The main limitations of this approach however are:

- (1) The cellulose loses its transparency as well as becomes black in color, and
- (2) Changes in conductivity and magnetization with repeated cycles of bending to demonstrate flexibility have not been reported.

These studies would be very relevant for practical application of these nanocomposite sheets.

The loss of optical transparency and color of bacterial cellulose due to functionalization can be a limitation in certain applications. In order to overcome the loss of color, Sriplai *et al.* (2018) have developed a 'sandwich' strategy to overcome the blackening and synthesized a white, magnetic, xerogel paper. The black magnetic paper consisting of CoFe_2O_4 nanoparticles dispersed in the cellulose reticulate structure was sandwiched between two white cellulose sheets consisting of ZnO nanoparticles. The ZnO nanoparticles in cellulose provide 'whiteness' while the CoFe_2O_4 nanoparticles induce magnetic response, Fig. 3(a). The magnetic nanoparticles loading was $\sim 43 \text{ wt\%}$ and the whitening ZnO nanoparticles was either 24 wt% or 39 wt%. The whitening index of the resulting sandwich xerogel paper increased from $\sim 27\%$ to $\sim 85\%$ due to the addition of two 39 wt% ZnO

Fig. 1 (a) Variation in electrical resistance of Ni nanoparticle embedded BC nanocomposite with increase in the concentration of NiCl_2 in the precursor solution from 0.02 to 0.05. Inset: Sharp drop in electrical resistance by several orders of magnitude as a function of precursor concentration shows the onset of conductivity. (b) Increase in magnetic energy product (BH_{max}) of NiBC nanocomposite with increasing concentration of NiCl_2 precursor solution.

Fig. 2 (a) Field dependent isothermal magnetization, M of FeNi_3/BC nanocomposite xerogel hot pressed at 60° at 9 MPa (FNBC9) at temperatures of 5, 50 and 300 K. Inset: Hysteresis loops at low fields for FNBC9 at 5, 50 and 300 K show coercivity and hence ferromagnetic behavior. Photograph illustrates the magnetic actuator response of the xerogel sheet. (b) Comparison of temperature dependent d.c. electrical conductivity of FNBC9 and FNBC26 xerogels indicating metallic conduction behavior. Photograph demonstrates electrical conductivity at room temperature.

nanoparticles containing hydrogel sheets on either side of the magnetic hydrogel. The specific magnetization of the resulting xerogel paper is about 20 emu g^{-1} , $\sim 1/4$ the specific magnetization of bulk CoFe_2O_4 . This work clearly shows that a white magnetic paper can indeed be synthesized albeit by the addition of two ZnO-nanoparticle containing papers. This work, like the earlier work wherein metal/alloy nanoparticles were introduced into bacterial cellulose, does not clearly demonstrate flexibility of the paper except for a tensile test. The tensile test only proves that the ductility and strength of the white, sandwich paper, and decreases compared to that of bacterial cellulose, [Fig. 3\(b\)](#).

One physical property, which is of extreme importance for any material to be used in electronic devices is its electrical conductivity. Bacterial cellulose lacks electrical conductivity due to the nature of bonding that exists between the different elements in it, although it is predominantly composed of carbon. Hence in order to induce a conducting behavior to this cellulose, various strategies such as incorporation of different types of conducting secondary phase materials varying from metals to carbon nanotubes and polymers have been explored. Most recently, Thiruvengadam and Vitta demonstrated that introduction of metal and alloy nanoparticles such as Ni and permalloy achieves the dual purpose of imparting electrical conductivity together with magnetic sensitivity ([Thiruvengadam and Vitta, 2017a,b](#)). These nanoparticles, however, are not completely biocompatible and if used in electronic implants or devices in the human body, tend to display cellular toxicity. Hence for bioelectronic device applications, secondary phase materials which are non-toxic to the human body environment need to be selected.

Recently, feasibility of making electrically conducting bacterial cellulose films consisting of noble, bio-inert elements such as Ag and Au has been demonstrated. [Lv et al. \(2018\)](#) synthesized bacterial cellulose film and Ag nanowires of size 196 nm width and 150 μm long separately. These nanowires were then spread onto BC film by suction filtering method, which consists of filtering the

Fig. 3 (a) The photograph shows clearly the formation of white magnetic paper due to sandwich strategy. MBC and ZNC represent magnetic BC and ZnO containing BC respectively, (b) The mechanical behavior, strength and tearing index of the different xerogel sheets is shown here.

homogeneously dispersed solution of nanowires through the BC film acting as the filtering medium. This resulted in the formation of Ag nanowire-containing film on BC and imparted electrical conductivity. It is however, not very clear if the 150 μm long Ag wires are retained on the top of BC or if they indeed penetrate into the BC film to provide bulk conductivity. This appears to be a major limitation of this approach to impart electrical conductivity to BC. Moreover, it is not clear whether the Ag nanowires undergo rupture after cyclic loading and the subsequent effects on electrical conductivity have not been demonstrated in this work. Khan et. al. followed a similar approach of synthesizing the two components, BC film and Au nanoparticles separately and subsequently introduced the Au nanoparticles into the BC film by soaking the BC pellicle in a solution containing these particles (Khan et al., 2018). In order to ensure complete electrical conductivity, a conducting polymer, PEDOT:PSS was also incorporated extrinsically by immersing the BC-Au nanoparticle film into the PEDOT:PSS solution. The Au nanoparticles varied in size from ~ 5 to 20 nm and were attached to the surface while the amorphous conducting polymer coated these fibers as well as filled the pores of the BC fiber structure. Incorporation of two electrical conductors i.e., Au nanoparticles and PEDOT:PSS polymer resulted in increasing the conductivity of Au filled BC from $2.95 \times 10^{-2} \text{ S cm}^{-1}$ to 16.65 S cm^{-1} , an increase in two orders of magnitude. Exposure of these films to osteoblast cells, commonly found in the extracellular matrix of bones, showed that these cells continued to grow even after 3 days with no cytotoxicity change compared to pure BC, Fig. 4(a) and (b). These studies clearly indicate the potential of developing biocompatible, non-toxic BC based electrically conducting films which can be used in implantable devices.

One of the biggest requirements of modern technology is sensors i.e., devices that can convert an external stimulus into change in magnitude of the intrinsic property of the material. Among several parameters that define the quality of a sensor, one of them is its sensitivity which is a measure of the maximum magnitude of intrinsic property change that can be created in the shortest possible time in response to an external stimulus. Hosseini et al. (2018) synthesized a BC composite with multiwalled carbon nanotubes incorporated into the cellulose matrix during the growth stage of cellulose itself. Various amounts of MWCNTs were introduced into the culture medium and it was found that the resulting BC has MWCNT incorporated into it. The composite exhibits enhanced electrical conductivity of $\sim 10^{-2} \text{ S m}^{-1}$ for a volume concentration of 0.0041 corresponding to percolation attainment. The strain sensitivity of this composite was investigated at two different strains of 2% and 8% for up to 10 cycles by measuring the change in resistivity of the composite. The strain sensitivity was reversible up to 10 cycles for low values of strain i.e., 2%, while for the higher strain, irreversible changes in the composite lead to deteriorating performance, Fig. 5(a)–(c). The gauge factor which is a measure of strain sensitivity was 21, a high value compared to typical strain sensors based on resistive metallic bridges. The strain sensitivity was

Fig. 4 (a) Morphology of animal osteoblast cells attached to BC and BC/AuNPs-PEDOT:PSS composites as observed under a Field-Emission Scanning Electron Microscope (FE-SEM). The images were obtained after an 8-h incubation period and after a prolonged 3-day incubation period for both samples. (b) Comparison of cell viability on BC and BC/AuNPs-PEDOT:PSS using 3-dimethylthiazol-2,5- diphenyltetrazolium bromide (MTT) assay. No significant difference in cell viability was observed after incubation for 1 day and 5 days.

found to be retained after 100 twisting cycles and 100 cycles of 180° bending, **Fig. 6(a)** and **(b)**. These results clearly demonstrate the potential of this strain sensor for practical application under different conditions.

Energy Devices

Another physical property of a material which is of importance for sensors and also energy conversion is 'piezoelectric' nature which facilitates interconversion of electric field and mechanical stress or strain. These materials respond to external stress by generating an electric field due to the displacement of ions from their equilibrium positions resulting in polarized structure formation. Such materials are extremely important for conversion of mechanical stress into electrical power. For e.g., when incorporated in to shoes, they can convert human mechanical working energy into electrical power. Bacterial cellulose being made of polar molecules i.e., saccharides, can indeed exhibit piezoelectric behavior. Their random spatial arrangement, however, results in very low conversion efficiencies which prevent them from being used in the native state for this application. In order to enhance the polarizability of this material, cellulose nanocrystals have been extracted and made into thin films containing highly aligned layers of these nanocrystals. An alternative approach is to incorporate a piezoelectric secondary phase into the bacterial cellulose reticulate structure. Zhang *et al.* (2018) used this alternate approach and incorporated Vanadium doped ZnO nanoparticles to make nanogenerators. The Vanadium doped ZnO nanoparticles were in situ synthesized in the BC structure and it resulted in the formation of 5 μm particles which in turn were made of ~100 nm thick ZnO plates. The exact amount of ZnO particles loading, however, was not determined. To determine the amount of power that can be generated by bending action, the composite film was mounted onto Kapton substrate with the top and bottom faces acting as two electrodes, **Fig. 7(a)**. The maximum output current density and voltage reached 80 nA cm⁻² and 1.5 V corresponding to a power density of 60 nW cm⁻² for a matching external load

Fig. 5 Variation in relative resistance of BC/MWCNT nanocomposite aerogel for ten loading-unloading cycles at strain rate of (a) 2% and (b) 8%. (c) Variation in maximum normalized strain rate with cycle number for the aerogel based strain sensor over 10 cycles. It is seen that the strain sensing performance decreases at higher strain values.

Fig. 6 Change in resistivity on (a) twisting and (b) bending of BC/MWCNT nanocomposite. Figure shows very little change over 100 cycles demonstrating its flexibility.

Fig. 7 (a) Schematic and photographs show bending stage that consists of nanogenerator (NG) device attached to Kapton substrate (b) Output voltage in forward and reverse mode and (c) Current density under forward and reverse mode of operation for V-doped ZnO/BC based Piezoelectric Nanogenerator (PENG) film. (d) Variation in the output current and output power density of the nanocomposite film with load resistance.

resistance of 70 MΩ, Fig. 7(b)–(d). The current density and voltage are an order of magnitude higher compared to those of either pure BC or undoped ZnO, clearly indicating the role of Vanadium doping. The current density generated by the nanocomposite film increased linearly with increasing bending angle, an effect of increased strain in the film. The composite film retains its output performance even after being subjected to 10,000 bending and releasing cycles. This work demonstrates the potential of the concept of mechanical to electrical energy conversion. Use of materials with higher piezoelectric response can result in significantly higher energy conversion efficiencies.

The internet of things (IOT) has resulted in a paradigm shift in the use of communication devices such as hand held telephones or mobiles which are becoming powerful with several functionalities. Since these devices require wireless electrical power, batteries have gained significant importance. The size, power density, discharge/charge time scales and longevity of these batteries is being continuously improved due to the discovery of new materials and designs. The three basic components of a battery are the two electrodes and the separator. The separator in the battery plays a crucial role in maintaining the two electrodes physically apart as well as storing the electrolyte. It facilitates ion exchange across its thickness and hence should possess sufficient porosity together with robustness. The decreasing size of mobiles requires the batteries to be compact without compromising its power delivering capacity. These requirements have resulted in the development of thinner separators with sufficient strength and porosity. In this context, Xu *et al.* (2017) have developed a BC/Al₂O₃ composite film for lithium ion battery separator. The composite membrane was made by in situ synthesis of Al₂O₃. This results in uniformly coating the BC fibers with an amorphous Al₂O₃ layer and thus retains the porous nature of BC. The retention of porous structure leads to an enhanced electrolyte uptake capacity of ~4.5 mg cm⁻², which is twice that of a conventional polymer separator, PP-PE-PP, Fig. 8(a). The enhanced electrolyte uptake also results in increasing the ionic conductivity from 3.39 mS cm⁻¹ for the polymer separator to 4.91 mS cm⁻¹, Fig. 8(b). The enhanced Li-ion transport capability leads to better battery performance, Fig. 8(c). Although, the incorporation of Al₂O₃ improves the electrochemical performance, it results in decreasing the elasticity of the membrane. This could possibly limit application of this BC/Al₂O₃ composite membrane from being used in batteries for flexible electronic applications.

Fig. 8 (a) Comparison of electrolyte uptake capacity of BC/Al₂O₃ separator film with that of commercial separator PP-PE-PP, as a function of time, (b) Linear sweep cyclic voltammograms of commercial separator PE-PP-PE and BC/Al₂O₃ separator film at scan rate of 1.0 mV s⁻¹. (c) Comparison of rate capacity of the cells using PE-PP-PE and BC/Al₂O₃ separators at different C-rates.

Capacitor is a device which stores electrical energy in the form of separated charges and delivers it on demand. Capacitors are used in a variety of applications and range in capacity by several orders of magnitude from pico Farads to several Farads. The advent of modern electronic devices varying from hand held communication devices to personal computers have imposed a demand for the development of capacitors with highest possible specific capacitance. This has driven the demand for ultra-capacitors or supercapacitors with specific capacitance values of the order of 10³ F g⁻¹. These specific capacitance values coupled with flexibility for the capacitor leads to using BC as a highly suitable medium. Peng *et al.* (2017) used flexible, biodegradable BC to make supercapacitors with polypyrrole and CuO incorporated in it. The CuO nanoparticles were incorporated into the BC by in situ synthesis and subsequently the polypyrrole was infiltrated by dipping the BC/CuO membrane into an aqueous solution containing the polymer. Various tests were performed in order to study the capacitor characteristics. It was found that the specific capacitance decreased with increasing voltage scan rate as well as the cycling. The highest specific capacitance was found to be 897 F g⁻¹ which decreased with charging rate as well as cycling indicating that the cycling stability is not high. The thermal stability of the composites was low due to the incorporation of CuO nanoparticles. These studies show the feasibility of making flexible supercapacitors using BC membrane as a template.

In summary, BC is a naturally sustainable, biodegradable and biocompatible polymer which can be used for a variety of applications. The hierarchical fibrous structure together with high degree of crystallinity compared to plant cellulose imparts high mechanical strength and flexibility. The reticulate structure with different sized pores, ranging from few nanometers to microns, facilitates the incorporation of a wide variety of materials. This versatility allows BC to be used as a template to insert metals, alloys, oxides and polymers and thus impart a range of functionalities from electrical conductivity to piezoelectricity and magnetism to optical transparency. With an increasing demand to develop environmentally benign materials which are sustainable and at the same time deliver a wide range of functionalities, BC will find increasing demand. This will also lead to a growth in large scale production of BC using different and novel methodologies.
